15

16 **Abstract:**

17 Chloride ion penetration resistance (CPR) of concrete containing fly ash (FA)/silica
18 fume (SF) against combined freezing-thawing and chloride attack was studied. The
19 total charge passed, immersed in tap water and sodium chloride solution, subjected to
20 50 freezing-thawing cycles was evaluated. It was found that immersed in tap water,
21 SF had more evident improvement on concrete's resistance to combined effects than

*Corresponding author at: Department of Civil & Environmental Engineering, Brunel University London, Uxbridge, Middlesex UB8 3PH, United Kingdom. E-mail address: dezhi.wang@brunel.ac.uk (Dezhi Wang).

22 FA. Sodium chloride solution immersion for 41d prior to test was more aggressive
23 than tap water. After 50 freezing-thawing cycles, CPR of concrete with FA increased,
24 while that with SF decreased. Interaction between freezing-thawing and chloride
25 attack accelerated concrete deterioration.

30

31 **1. Introduction**

32 Concrete is versatile and the most widely used construction material in the world. But
33 owing to aggressive marine exposure environment and the extensive use of de-icing
34 salts in many countries, chloride induced corrosion becomes one of the most common
35 causes of degradation of reinforced concrete structures [1-4]. The first effect of
36 chloride ions is physical salt attack leading to surface cracking and scaling which is
37 similar in appearance to freezing-and-thawing damage and total disintegration of
38 low-quality concrete [5]. Another effect is that chloride ions are the most important
39 cause of corrosion of embedded rebar. When chloride ions penetrate concrete cover
40 and arrive at reinforcement bars, as their amount accumulates, the passive film may
41 break down (i.e. de-passivation) and corrosion of embedded rebar can then initiate [6,
42 7]. The accumulation of corrosion products can build up the swelling pressure around
43 the rebar resulting in cracking or spalling of concrete[8], which in turn facilitates the

44 ingress of moisture, oxygen, and chlorides to the rebar and accelerates rebar corrosion
45 [9]. Pitting corrosion is another threat to RC structures in a chloride environment [10]
46 and is a type of more serious corrosion on structural safety than general corrosion[11,
47 12], since it has resulted in quite high loss of cross-sectional area of reinforcement
48 bars [13] and structural damages[14], or in extreme situations, the final collapse of the
49 structure.

50 Chloride penetration in concrete can be characterized by the chloride diffusion
51 coefficient and the binding ability of matrix-forming solids [15]. In concrete,
52 chlorides can be chemically bound with cement's C3A or C4AF phases (e.g., Friedel's
53 salt) [16], or physically hold to the surface of hydration products (e.g., adsorption on
54 C-S-H) [3, 17]. Chloride diffusion depends on pure diffusion for water-saturated
55 concrete and capillary absorption of salty water for non-saturated concrete [18].

56 Recently, there are several studies reported in literature on the transport of chloride
57 ions in concrete and numerical models developed to simulate the process [7, 19-22].
58 Meanwhile, chloride penetration into concrete is governed by many factors. Due to
59 the chemical and physical bond between chloride ion and hydrated product of cement
60 changing the micro-structure, the chloride diffusion coefficient changes during the
61 exposure period and decreases with an increased period of exposure [23-26]. Nobuaki
62 [27] and Page [28] both studied chloride ions diffusion in concrete at different
63 temperatures and the results reveal that the rates of diffusion of Cl^- in concrete rises
64 with increases in temperature. In real environments, concrete structures are subjected
65 to various environmental factors acting in a combined and possibly synergistically

66 physical and chemical manner to accelerate the destruction process. Therefore, it is
67 significant to study chloride resistance of concrete under combined deteriorating
68 factors to obtain sufficient information on concrete durability. Chloride penetration
69 and carbonation of concrete are often considered to be the most significant coupled
70 deterioration factors and numerous studies have taken both factors into account in
71 assessing concrete durability [29-35]. As reported by Chindaprasirt [29] , Tumidajski
72 [31] and Houst [36], carbonation decreases chloride penetration and diffusivity in
73 ordinary Portland cement (OPC) mortar and concrete. While other test results [30, 34,
74 35] indicate that chloride penetration is accelerated when the carbonation process is
75 combined with the chloride ingress due to liberate bound chloride. The carbonation
76 effect on chloride penetration is controversial and considered to depend on the types
77 and mix proportions of concretes [29, 33, 35]. Initial cracks in concrete significantly
78 influence chloride penetration and the influence of crack width and depth has been
79 experimentally and numerically studied. It is clear that chloride transport is very rapid
80 along and across crack boundaries [37]. Concrete specimens are made with artificial
81 cracks by means of the positioning and removal after approximately 4 h of thin copper
82 sheets inside the specimen[38]. These copper sheets have a thickness of 0.2 mm, 0.3
83 mm or 0.5 mm. The copper sheets are placed at a depth in the concrete specimen of 5
84 mm, 10 mm, 15 mm or 20 mm. The test results also indicate that the penetration depth
85 increases with an increasing notch depth and that the influence of notch depth is more
86 pronounced for longer test duration while the influence of notch width is not clear [38,
87 39]. The chloride permeability of a concrete is influenced significantly by loading

88 style and critical stress [40-43]. The application of static loading up to 90% of the
89 ultimate strength had little effect on chloride permeability while load repetitions at the
90 maximum stress levels of 60% or more caused chloride permeability to increase
91 significantly [41].

92 In addition, drying and wetting cycles are always identified as the most unfavorable
93 environment condition for reinforced concrete structure subjected to chloride-induced
94 deterioration processes and it accelerates the ingress of chloride ions and affects
95 concrete durability [44, 45].

96 Investigations on chloride penetration resistance of concrete have also been conducted
97 in concrete science and engineering community, but studies on the effects of chloride
98 ion on deterioration of concrete with FA and SF under combined freezing-thawing and
99 chloride attack is very limited in literature. Rapid chloride permeability test (RCPT)
100 is the most widely specified durability test method and is standardized by ASTM.

101 The total charge passed (in Coulombs), the result of RCPT, provides a rapid
102 indication of its resistance to the penetration of chloride ions and is calculated via
103 Equation (1). In this research, concrete's total charge passed, immersed in tap water
104 and sodium chloride solutions, subjected to 50 freezing-thawing cycles was evaluated.

105 The influence of FA and SF replacement level of OPC and sodium chloride
106 concentration on durability of concrete under the combined freezing-thawing and
107 chloride attack was also investigated.

108

109 **2. Experimental program**

110 **2.1 Materials**

111 42.5 R Portland cement, manufactured by Saima Cement Manufacturing Company of
112 Ningxia, China conforming to EN197-1:2009, was used for preparing concrete in this
113 research and its physical and mechanical properties are listed in Table 1. Table 2
114 presents the chemical composition of the cement, FA and SF used in this study as
115 partial replacement of OPC. Crushed limestone aggregates were used as coarse
116 aggregates and washed mountain sand as fine aggregates, and the sieving curves are
117 presented in Fig.1. The fineness modulus of fine aggregates was evaluated
118 conforming to ASTM C136-01 and the results are presented in Table 3. Tap water was
119 used for mixing concrete. A commercially available naphthalene-based water reducer
120 (i.e. FDN, produced by MUHU Concrete Admixture Ltd.) was used to keep concrete
121 slump between 80 and 100 mm and its chemical characteristics are listed in Table 4.
122 Sodium chloride anhydrous with 99.5% purity and sodium hydroxide anhydrous with
123 99.0% purity were used for making chlorate solutions as the chloride attack source.

142 **2.2 Mix proportion and specimen preparation**

143 The actual mix proportions in terms of 1 m³ concrete for the mixtures investigated in
144 this study are given in **Table 5**. In order to investigate the effect of FA and SF on the
145 resistance of concrete to combined freezing-thawing and chloride attack, **the total**
146 **binder content of all mixtures was 500 kg/m³ according to Wu[46]** and concrete
147 mixtures were prepared with w/b ratios of 0.38 and 0.33, respectively. In each group,
148 concrete mixtures with three different FA contents (i.e. of 10%, 15% and 25% by
149 weight of cementitious materials (i.e. OPC + FA + SF)), three different silica fume
150 contents (i.e. of 5%, 8% and 11% also by weight of cementitious materials) as partial
151 replacement of OPC were prepared and tested.

152 Cubic specimens with the dimensions of 100 ×100 ×100 mm³ were prepared for
153 measuring compressive strength and cylinder specimens with (100±1) mm in diameter
154 and (50±2) mm in height for assessing Chloride Ion penetration resistance. Concrete
155 mixtures were prepared by a single horizontal-axis forced mixer. After moulded,
156 concrete specimens were placed in a curing room with temperature of (20±5)°C for 24
157 hour. Then they were demoulded and immersed in tap water with temperature of
158 (20±2)°C for another 27 days, which is referred as 28 days standard curing in this
159 paper. Concrete specimens for measuring compressive strength and Chloride Ion
160 penetration resistance were prepared for assessing long-term performance and
161 durability of ordinary concrete.

165

166 **2.3 Chloride ion penetration resistance assessment**

167 For assessing effects of chloride concentration on Chloride Ion penetration resistance

168 of concrete, cylindrical concrete specimens with (100±1) mm in diameter and (50±2)

169 mm in height cured standardly for 28 days were then immersed in tap water and

170 designated solution (i.e. 4% and 10% by wt. sodium chloride solutions), respectively,

171 for another 41 days. Conforming to ASTM C1202-12, the rapid chloride penetration

172 test (RCPT) was proceeded as following. First, cylindrical concrete specimens were

173 placed in a vacuum pump with its pressure decreased to less than 5000 Pa within 5

174 minutes and maintained the pressure for 3 hours; then concrete specimens were

175 immersed in distilled water at the vacuum pressure for 1 hour followed by being

176 immersed for (18±2) hours at normal ambient pressure; and finally one side of the

177 cylindrical specimen containing the top surface was filled with 3.0 % NaCl solution

178 and the other side of with 0.3 mol/L NaOH solution. During the 6 hours RCPT test,
179 temperatures of the specimen and the solutions were targeted to be between 20 and
180 25°C and they were recorded once every 5 minutes to ensure the target was reached.
181 The total charge passed during the RCPT test was measured and calculated via
182 Equation (1).

$$183 \quad Q = 900(I_0 + 2I_{30} + 2I_{60} + \dots + 2I_t + \dots + 2I_{300} + 2I_{330} + I_{360}) \quad (1)$$

184 where Q in Coulombs is the total charge passed; I_0 in Amperes current immediately
185 after voltage is applied; I_t in Amperes current at t min after voltage is applied.

186

187 **2.4 Freezing-thawing resistance assessment**

188 To assess concrete's resistance to combined freezing-thawing and chloride attack,
189 cylindrical concrete specimens with (100±1) mm in diameter and (50±2) mm in
190 height were cured standardly for 56 days, then they were subjected to rapid
191 freezing-thawing cycle test in tap water and designated solution (i.e. 4% and 10% by
192 wt. sodium chloride solutions), respectively. Conforming to ASTM C666/C666M-03,
193 a standard rapid freezing-thawing cycle lasted for 6 hours and was proceeded as
194 following: a cylindrical concrete specimen was frozen in the tap water or designated
195 sodium sulfate solution for 3 hours at -18(±2)°C, and subsequently it was thawed for
196 3 hours in water at 5(±2)°C. All concrete specimens were subjected to 50 such
197 freezing-thawing cycles. After that the RCPT was conducted. The deterioration
198 coefficient of total charge passed during the RCPT test was calculated via Equation
199 (2).

200
$$\lambda = \frac{Q_c}{Q_s} \tag{2}$$

201 where λ in % the deterioration coefficient of total charge passed; Q_c and Q_s in
202 Coulombs the total charge passed of a concrete specimen after subjected to combined
203 freezing-thawing and chloride attack and to solely freezing-thawing attack in tap
204 water, respectively.

205

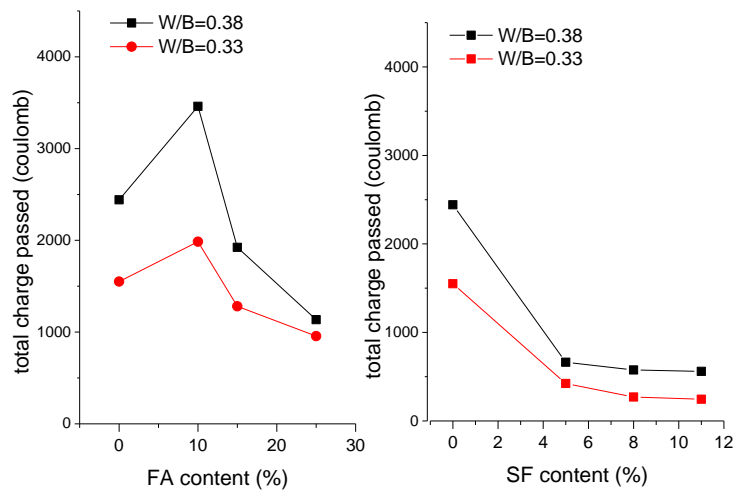

206 2.5 Observation under the Scanning Electron Microscopy (SEM)

207 The morphology and microstructure observation under SEM (KYKY2800B) from
208 Ningxia University were carried out on the specimens in order to understand the
209 influence of freezing-thawing and chloride attack. SEM specimens were dried in
210 drying oven for 48 hours at (80 ± 5) °C, and subsequently specimens' surfaces were
211 coated using a gold sputter coater to eliminate effects of charging during micrograph
212 collection.

213

214 3. Results and discussion

215 3.1 FA or SF dosage and chloride ion penetration resistance

216

217 Fig.2 Total charge passed of concretes with various FA and SF contents

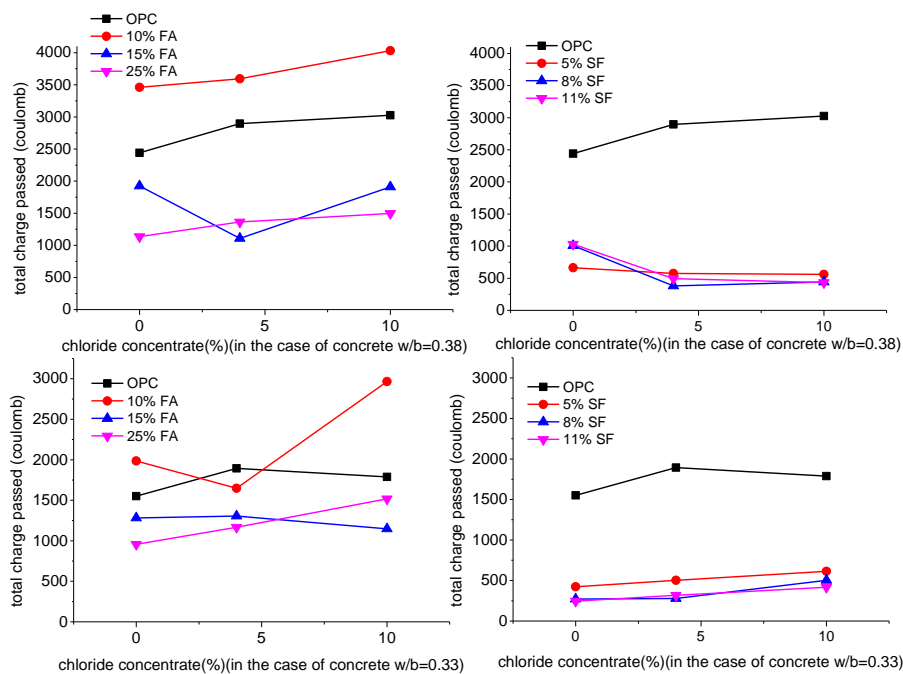

218

219 Measured total charge passed of the concrete specimens with various FA and SF
 220 contents after immersed in tap water for 69 days (i.e. 28 days + 41 days) is presented
 221 in Fig.2. The test results demonstrated that in general concrete's total charge passed
 222 actually decreased, as the FA or SF dosage increased and it was obvious that SF had
 223 more evident improvement on concrete chloride penetration resistance (i.e. on
 224 reducing total charge passed) than FA. Cured in tap water, concrete specimens with
 225 10% FA had the highest total charge passed (i.e. 3460.1C in case of the
 226 water-to-binder ratio of 0.38 and 1985.2 C in case of the water-to-binder of 0.33) than
 227 concrete specimens with other FA dosages, while concrete with 25% FA had the
 228 lowest value (i.e. 1135.1C with a water-to-binder ratio of 0.38 and 955.8C with a
 229 water-to-binder ratio of 0.33). In case of concretes with SF, the total charges passed
 230 were all less than 1000C and the higher chloride penetration resistance can be found
 231 from concretes with higher FA and SF dosage which exhibited lower total charge

232 passed. According to ASTM C1202, C-8 and C-3 mixtures were classified as
 233 moderate (2000-4000 coulombs) and low (1000-2000 coulombs), respectively, level
 234 of chloride ion penetrability, FA25-8 as low (1000-2000 coulombs) level of chloride
 235 ion penetrability, while FA25-3 and all concretes with SF as very low (100-1000
 236 coulombs) level of chloride ion penetrability.

237

238 3.2 Sodium chloride attack and chloride ion penetration resistance

239

240 Fig.3 Total charge passed of concretes immersed in sodium chloride solutions with
 241 various concentrations

242

243 The cylindrical concrete specimens were cured standardly for 28 days, then they were
 244 immersed in 0, 4% and 10%, respectively, sodium chloride solutions by wt. % for
 245 another 41 days and chloride ion penetration test was conducted immediately after 41

246 days immersion. Fig.3 presents the evolution of the total charge passed of concretes
247 exposed to sodium chloride solutions with various concentrations. Similar trend was
248 observed in concretes with different FA or SF contents. The results indicated that
249 under the two water-to-binder ratios (i.e. $w/b = 0.38$ and 0.33), sodium chloride
250 solution immersion for 41 days prior to the test was more aggressive than tap water
251 and 10% sodium chloride solution caused the largest rise in total charge passed. In the
252 case of w/b of 0.38, total charge passed of concretes with 0, 10%, 15% and 25% by
253 weight FA immersed in 10% sodium chloride solution had raised to 124.0%, 116.5%,
254 99.2% and 131.9 %, respectively, of their corresponding original value, and in the
255 case of $w/b = 0.33$, the counterpart value was 115.4%, 149.4%, 89.6% and 158.8%,
256 respectively. As for $w/b = 0.38$ concretes with 5%, 8% and 11% SF by weight, total
257 charge passed had raised to 155.2%, 85.8% and 77.4 %, respectively, of their
258 corresponding original value; and for $w/b = 0.33$ concretes, the counterpart value was
259 144.8%, 185.9% and 170.3%, respectively.

260 In addition, 10% FA decreased chloride penetration resistance and had higher total
261 charge passed than OPC concrete not only in tap water but also in sodium chloride
262 solution while 15-25% FA can significantly improve chloride penetration resistance in
263 the same condition. All of the three SF dosages played more actively important role
264 than FA in raising the chloride penetration resistance and all concrete mixtures with
265 SF were at very low (100-1000 coulombs) level of total charge passed, indicating very
266 low level of chloride ion penetrability.

267

3.3 50 freezing-thawing cycles and chloride ion penetration resistance

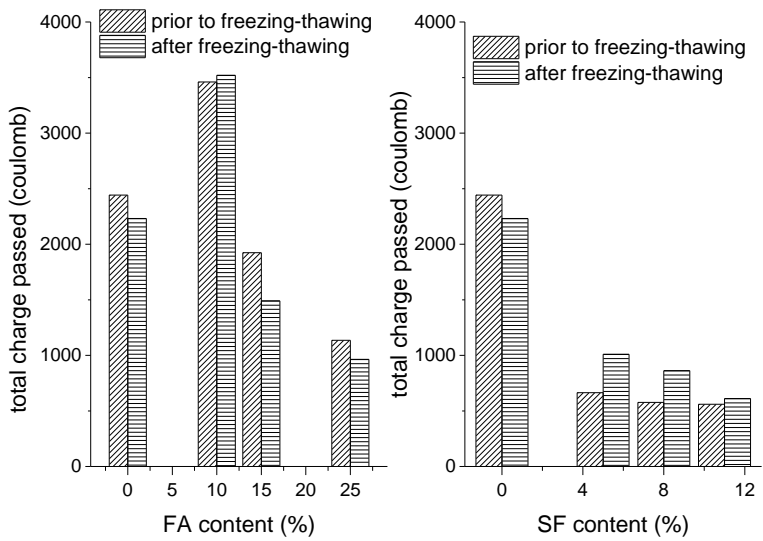

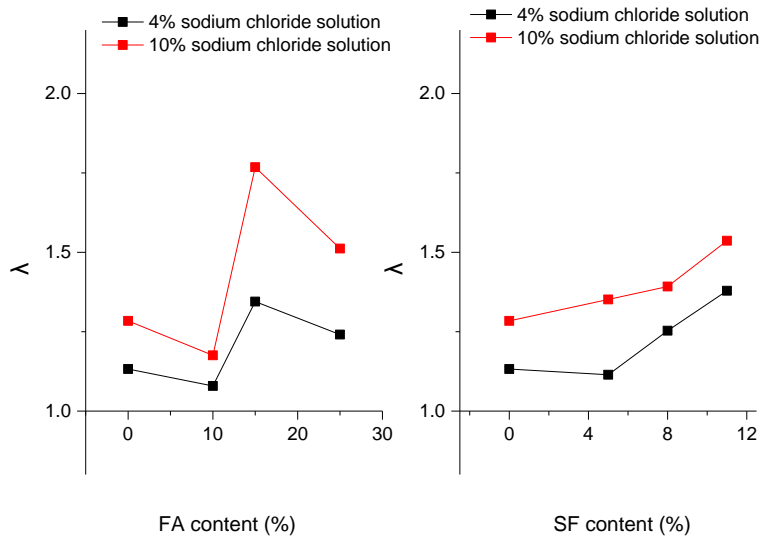

Fig.4 Total charge passed of concretes after 50 freezing-thawing cycles.

The cylindrical concrete specimens were cured under standard curing condition for 56 days and then subjected to freezing-thawing cycles in tap water, 4% and 10% sodium chloride solutions up to 50 cycles, which lasted around 13 days, and subsequently chloride ion penetration test were conducted. The total charge passed of various concretes exposed to tap water under freezing-thawing cycles are depicted in Fig.4 (for concretes with w/b=0.38). There was a significant decrease in total charge passed ranged from 8.6% to 22.6% over the test period for the concrete with 15% and 25% FA by weight, respectively, while a slight increase by 1.7% for concrete with 10% FA by weight. In the case of concrete with SF, the total charge passed increased by 52.2%, 49.7% and 9.0% at the SF content of 5%, 8% and 11% by weight, respectively. It can be concluded that under 50 freezing-thawing cycles, chloride ion penetration

284 resistance of concrete with FA increased while that of concrete with SF decreased.

285

286 3.4 Chloride ion penetration resistance against combined 287 freezing-thawing and chloride attack

288

289 Fig.5 Deterioration coefficient of total charge passed of concretes exposed to tap
290 water and sodium chloride solution after 50 freezing-thawing cycles.

291

292 Concrete deterioration was associated with the interaction between freezing-thawing
293 and chloride attack. Via Equation (2), if $\lambda > 1$, it means the interaction accelerates
294 concrete deterioration. If $\lambda < 1$, the interaction retards concrete deterioration. When λ
295 becomes larger or smaller, the accelerating or retarding effect on concrete
296 deterioration becomes more significant. In Fig.5 the interaction between
297 freezing-thawing and chloride attack accelerated the deterioration of all concrete
298 specimens, 10% sodium chloride solution demonstrated higher deterioration effect
299 than 4% solution. In the case of concretes with 15-25% FA, their λ values were

300 obviously higher than those of OPC concretes, while in the case of concretes with SF,
301 λ increased as the SF dosage increased. It can be concluded that when the FA dosage
302 was more than 15% or SF dosage more than 8%, both by weight, the acceleration
303 effect of the interaction between freezing-thawing and chloride attack on concrete
304 deterioration was more significant, and these concretes were more vulnerable to the
305 interaction and had the lower chloride ion penetration resistance against combined
306 freezing-thawing and chloride attack.

(d) SF8-8

321 Figs.7 SEM images of concrete with 25% FA, 8% SF by weight exposed to tap water

322 ((a) and (c)) and to 10% sodium chloride solution ((b) and (d)) after 50

323 freezing-thawing cycles

324

325 Figs.6 and Figs.7 present SEM images of concrete specimens at a depth of 5mm.

326 When concretes were exposed to tap water, there were no clear microcracks resulting

327 in a very compact microstructure, and this was the result of the pozzolanic reaction

328 (i.e. Figs. 6(a) and (e)). The use of pozzolanic materials (i.e. FA and SF) increases the

329 CSH, reduce the CH and the porosity in the cementitious matrix [47, 48]. The
330 decrease of total charge passed of concrete with pozzolanic materials was attributed to
331 the decrease of the porous system which is directly related to the electrical resistivity
332 [49] and the low water to binder ratio.

333 When concretes were exposed to sodium chloride solution up to 41 days, it can be
334 observed that there were not obvious differences in microstructures up to 1000 times
335 magnification (i.e. Figs.6 (a) and (b)), while at 5000 times magnification the concrete
336 specimen with 25% FA and 8% SF exposed to tap water had smaller pore and denser
337 structure than those to 10% sodium chloride solution (i.e. Figs.6 (c), (d), (e) and (f)).

338 When concrete specimens were exposed to 10% sodium chloride solution solutions up
339 to 50 freezing-thawing cycles (i.e. Figs.7), there were two different trends. Concrete
340 specimens with 25% by weight FA replacing OPC possessed compacter
341 microstructure than those in tap water, while the microstructure of the one with 8% by
342 weight SF replacing OPC would be looser after 50 freezing-thawing cycles.

343

344 **4. Conclusions**

345 Chloride ion penetration of concretes with w/b of 0.38 and 0.33 containing FA or SF
346 against combined freezing-thawing and chloride attack was investigated in this study.

347 The following conclusions can be drawn based on the experimental results.

348 (1) Immersed in tap water, concrete's total charge passed actually decreased as the
349 FA or SF dosage increased and, in comparison, SF had more evident
350 improvement on concrete chloride penetration resistance than FA. It was

351 clearly indicated that 15% and 25% by weight FA and all SF dosages were
352 more effective to reduce concrete total charge passed and to enhance chloride
353 penetration resistance. All concretes with SF were classified as at very low
354 (100-1000 coulombs) level of chloride ion penetrability.

355 (2) Sodium chloride solution immersion was more aggressive to concrete than tap
356 water and 10% sodium chloride solution caused the lowest chloride
357 penetration resistance. In addition, 15-25% by weight FA can significantly
358 improve chloride penetration resistance not only in tap water but also in
359 sodium chloride solution. All of the three SF dosages played more actively
360 important role than FA in raising the chloride penetration resistance and all
361 concretes with SF were at very low (100-1000 coulombs) level of chloride ion
362 penetrability when immersed in sodium chloride solution.

363 (3) After 50 freezing-thawing cycles in tap water, chloride ion penetration
364 resistance of concrete with FA increased, while that of concrete with SF
365 decreased.

366 (4) The interaction between freezing-thawing and chloride attack accelerated the
367 deterioration of all concrete specimens and 10% sodium chloride solution
368 demonstrated higher deterioration effect than 4% solution. Concretes with
369 more than 15% FA or 8% SF by weight replacing OPC had lower chloride ion
370 penetration resistance against combined freezing-thawing and chloride attack

371

372 **Acknowledgement**

373 The authors would like to acknowledge the National Natural Science Foundation of
374 China (through the grant 51368049 and 51668001), Ningxia First Class Discipline
375 Project (through the grant NXYLXK2017A03) and Ningxia University Subject
376 Development Project for sponsoring this research. The first author would also like to
377 acknowledge the China Scholarship Council for sponsoring his one-year visit to
378 Brunel University London where this paper was completed.
