## Highlights:

- Two-stroke operation was achieved in a four-valve direct injection gasoline engine;
- Shorter valve opening durations improved torque at lower engine speeds;
- The longer the valve opening duration, the lower was the air trapping efficiency;
- Higher exhaust backpressure and lower valve lift reduced the compressor work;

## Keywords:

- Supercharged two-stroke cycle engine
- Overhead poppet valves
- Variable valve actuation
- Gasoline direct injection

## Abstract

The current demand for fuel efficient and lightweight powertrains, particularly for application in downsized and hybrid electric vehicles, has renewed the interest in two-stroke engines. In this framework, an overhead four-valve spark-ignition gasoline engine was modified to run in the two-stroke cycle. The scavenging process took place during a long valve overlap period around bottom dead centre at each crankshaft revolution. Boosted intake air was externally supplied at a constant pressure and gasoline was directly injected into the cylinder after valve closure. Intake and exhaust valve timings and lifts were independently varied through an electrohydraulic valve train, so their effects on engine performance and gas exchanging were investigated at 800 rpm and

29 2000 rpm. Different exhaust backpressures were also evaluated by means of exhaust throttling. Air  
30 trapping efficiency, charging efficiency and scavenge ratio were calculated based on air and fuel  
31 flow rates, and exhaust oxygen concentration at fuel rich conditions. The results indicated that  
32 longer intake and exhaust valve opening durations increased the charge purity and hence torque  
33 at higher engine speeds. At lower speeds, although, shorter valve opening durations increased air  
34 trapping efficiency and reduced the estimated supercharger power consumption due to lower air  
35 short-circuiting. A strong correlation was found between torque and charging efficiency, while air  
36 trapping efficiency was more associated to exhaust valve opening duration. The application of  
37 exhaust backpressure, as well as lower intake/exhaust valve lifts, made it possible to increase air  
38 trapping efficiency at the expense of lower charging efficiency.

## 46 **Abbreviations**

47  $AFR_{CYL}$ : in-cylinder air/fuel ratio,  $AFR_{EXH}$ : exhaust air/fuel ratio, ATDC: after top dead centre,  
48 BDC: bottom dead centre, BP: backpressure, CA: crank angle, CAI: controlled auto-ignition, CE:  
49 charging efficiency,  $C_p$ : specific heat of air at constant pressure, ECR: effective compression ratio,  
50 EER: effective expansion ratio, EVC: exhaust valve closing, EVL: exhaust valve lift, EVO: exhaust  
51 valve opening, IMEP: indicated mean effective pressure, IVC: intake valve closing, IVL: intake  
52 valve lift, IVO: intake valve opening,  $m_{TRAP}$ : in-cylinder trapped air mass, LHV: lower heating value,  
53 LVDT: linear variable displacement transducer, MBT: minimum spark advance for best torque,  $\dot{m}$ :  
54 air mass flow rate,  $P_{AMB}$ : ambient pressure,  $P_{INT}$ : intake pressure, RGF: residual gas fraction, SOI:  
55 start of injection, SR: scavenge ratio,  $T_{AMB}$ : ambient temperature, TE: air trapping efficiency, UHC:

56 unburned hydrocarbon,  $V_{CLR}$ : clearance volume,  $V_{CYL}$ : in-cylinder volume,  $\dot{W}_C$ : compressor power  
57 requirement,  $[O_2]_{AMB}$ : ambient oxygen concentration,  $[O_2]_{EXH}$ : exhaust oxygen concentration,  
58  $\lambda_{CYL}$ : in-cylinder lambda,  $\lambda_{EXH}$ : exhaust lambda,  $\rho_{INT}$ : intake air density,  $\gamma$ : ratio of specific heats,  
59  $\eta_C$ : compressor isentropic efficiency,  $\eta_i$ : indicated efficiency,  $\eta_M$ : compressor mechanical  
60 efficiency.

## 61 1. Introduction

62 The concept of engine downsizing has been adopted as the most feasible solution to four-  
63 stroke spark-ignition engines to attend upcoming CO<sub>2</sub> emission legislations. Following this  
64 principle the engine operation region is shifted towards higher loads by decreasing its swept  
65 volume and the number of cylinders. Therefore, large improvements in fuel consumption are  
66 obtained from lower pumping losses at higher intake pressures. To ensure the same full load  
67 performance of larger engines, supercharging and/or turbocharging is used to improve the charge  
68 density [1]. The increased engine load and hence higher in-cylinder temperature/pressure results  
69 in greater structural and thermal stresses. The occurrence of knocking combustion becomes also  
70 more often due to more severe compression of the end-gas [2], as well as higher probability of  
71 low-speed pre-ignition [3][4]. Conversely, two-stroke engines have the inherent advantage of  
72 doubled firing frequency compared to four-stroke engines, so the same output torque can be  
73 achieved with one half the indicated mean effective pressure (IMEP). The lower engine load, and  
74 consequently reduced structural robustness required, has made the two-stroke cycle mostly used  
75 for light weight vehicles. Its application as range extender in hybrid electric vehicles has been also  
76 evaluated for such primarily reason [5]. In small engines the use of intake and exhaust ports is  
77 rather attractive considering production costs and complexity compared to four-stroke units. This  
78 justifies the success of crank-case mixture scavenged two-stroke engines for motorcycles and  
79 handheld equipment [6]. On the other end of two-stroke engine application field are the low-speed  
80 uniflow-scavenged marine engines, with displacements in the order of cubic metres and brake  
81 efficiencies in excess of 50% [7][8][9].

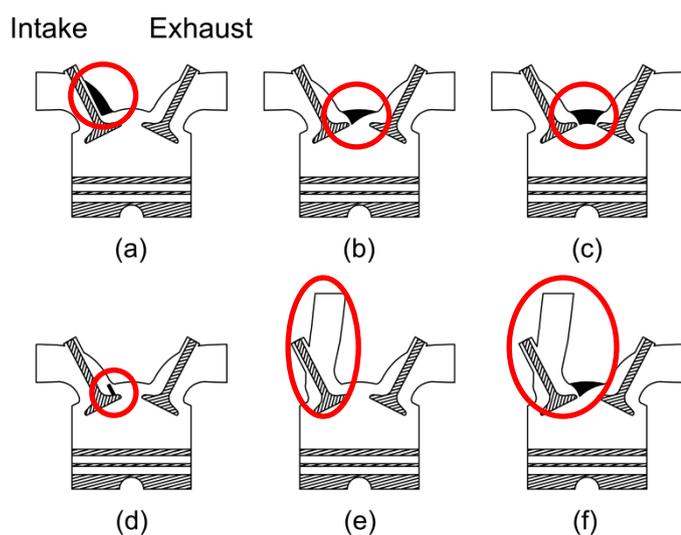

82 The use of two-stroke engines in passenger cars, although, is constrained by three main  
83 factors: irregular combustion at low loads, fuel short-circuiting in mixture-scavenged engines and  
84 crank train durability issues [10]. At low loads two-stroke engines present large portions of burned  
85 gases trapped in the cylinder. Such dilution increases the heat capacity of the charge and reduces  
86 the oxygen availability resulting in unstable combustion and misfire [11]. When an efficient  
87 management of residual gas is performed through exhaust throttling [12][13] or overhead  
88 intake/exhaust valves [14][15][16], controlled auto-ignition (CAI) combustion can be achieved. This  
89 combustion mode improves combustion stability and fuel consumption by means of short burning  
90 durations and lower heat transfer [17].

91 Fuel short-circuiting is the main cause of unburned hydrocarbon (UHC) emissions in  
92 crankcase-mixture-scavenged two-stroke engines [18]. The use of direct fuel injection has  
93 addressed it at the cost of more complex and expensive fuel metering systems [19][20][21].  
94 Despite such improvement, lubricant oil still needs to be added to the intake air to provide  
95 lubrication to the crank train components. To overcome this issue several concepts have been  
96 proposed, amongst which the uniflow-scavenged and the poppet-valve-scavenged are the most  
97 prominent. In such engines a conventional wet sump is employed similarly to that used in modern  
98 four-stroke engines. Two-stroke poppet valve engines have usually four overhead valves, which  
99 remain opened around bottom dead centre (BDC) every crankshaft revolution. Supercharger  
100 and/or turbocharger are responsible for supplying boosted intake air to scavenge the burned gases  
101 during the long valve overlap period. In the absence of ports, thermal distortion on piston and liner  
102 is avoided as the coolant jacket spreads uniformly around the cylinder [22]. Another advantage of  
103 poppet valve engines is the possibility of asymmetrical intake and exhaust valve operation [23]. In  
104 piston-controlled ported engines the gas exchanging is penalised at off-design conditions by the  
105 constant port timing, although the use of exhaust valves has partially addressed the issue [24].

106 Fuel short-circuiting in gasoline two-stroke engines with overhead valves can be readily  
107 avoided by direct fuel injection, although air short-circuiting from the intake to the exhaust system  
108 is still present. This is particularly found at high engine loads when great scavenging efficiencies  
109 are required to allow larger amounts of fuel to burn effectively. Several approaches have been

110 investigated to reduce air short-circuiting, such as intake port deflector [25], masked cylinder head  
111 [20], stepped cylinder head [26], intake valve shrouding [27][28], and vertical intake ports [29].

112 The intake port deflector seen in Figure 1 (a) performs well at low engine loads, although at  
113 higher loads it largely restricts the intake air flow [25]. With a cylinder head mask, as shown in  
114 Figure 1 (b), air short-circuiting can be improved at all operating conditions despite the reduction in  
115 valve effective curtain area. This approach was recently used in a light duty two-cylinder Diesel  
116 engine [30]. The stepped cylinder head presents similar intake flow performance to the masked  
117 approach, even though the exhaust valve curtain region is also restricted as seen in Figure 1 (c).  
118 The use of shrouded valves seen in Figure 1 (d) improves the air trapping efficiency. However,  
119 methods to prevent the valves from spinning during the engine operation add complexity to this  
120 approach [27][28]. A wide range of valve shroud angles between 70° and 108° were found to  
121 perform well in a single cylinder four-valve 370 cm<sup>3</sup> engine [31]. Finally, the vertical intake port  
122 seen in Figure 1 (e) promotes the least flow restriction amongst all methods, although when solely  
123 used it cannot ensure high scavenging with low charge short-circuiting [26]. When employed in  
124 conjunction with a masked cylinder head, the vertical intake port improves the port's discharge  
125 coefficient [32]. Such configuration seen in Figure 1 (f) was employed in this research as it  
126 demonstrates a compromise between in-cylinder scavenging and flow restriction.

127  
128 Figure 1 – Improvements in scavenging of two-stroke poppet valve engines: (a) intake port  
129 deflector, (b) masked cylinder head, (c) stepped cylinder head, (d) intake valve shrouding, (e)  
130 vertical intake port, and (f) masked cylinder head with vertical intake port.

131 The recent demand for high power density and low weight engines has renewed the interest  
132 in two-stroke poppet valve engines, particularly for application in diesel passenger cars [33][34]  
133 and hybrid electric vehicles [5][35]. Supercharged two-stroke engines with exhaust overhead  
134 valves have been also reported for use on general aviation and unmanned aerial vehicles [36].  
135 Hence, with numerous improvements on variable valve actuation systems over the years [37][38],  
136 their application on the two-stroke cycle has the potential to greatly improve engine operation.  
137 Also, exhaust port restriction has been widely employed in ported two-stroke engines to improve  
138 torque and emissions over the years [39][40]. In poppet valve two stroke engines, although, its  
139 use has been mostly evaluated through numerical simulation to demonstrate the side effects of  
140 turbocharging [41][42]. In this framework, the present research experimentally investigates the  
141 effects of several intake/exhaust valve timings on gas exchanging and performance of a two-stroke  
142 GDI engine with overhead poppet valves. The effects of exhaust throttling in conjunction with low  
143 and full exhaust valve lift are also evaluated to explore the possible effects of turbocharging and/or  
144 aftertreatment systems. Meanwhile, intake valve lift was varied to evaluate the role played by the  
145 cylinder head mask on engine performance and gas exchange process.

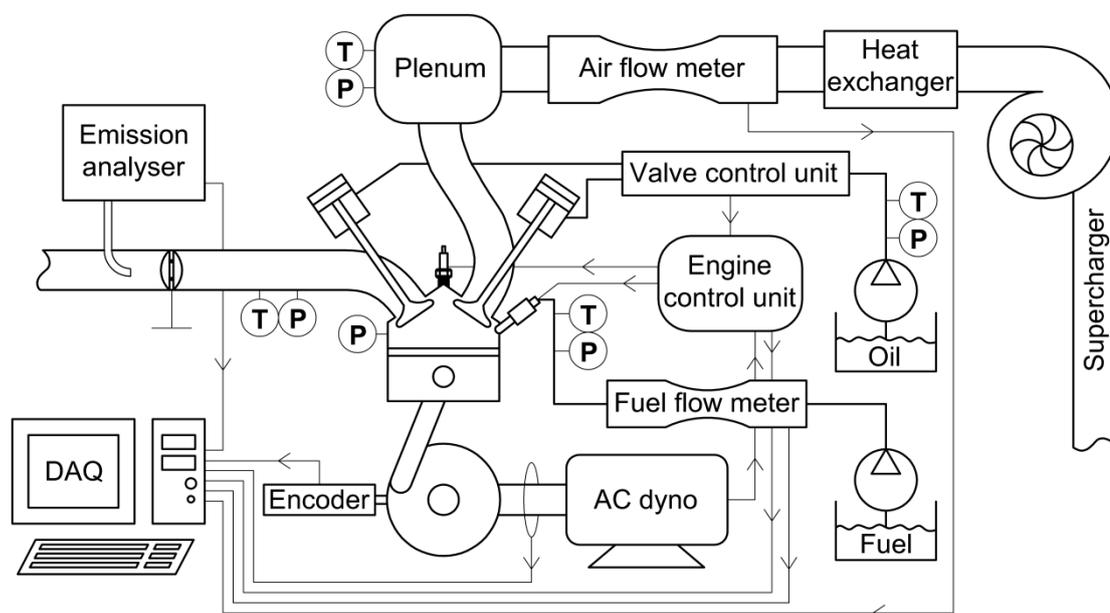

## 146 **2. Experiments**

### 147 2.1 Experimental setup

148 The experiments were carried out in a Ricardo Hydra engine equipped with a fully variable  
149 electrohydraulic valve train unit, which provided independent control over intake and exhaust  
150 valves [43]. The 350 cm<sup>3</sup> engine displacement resulted from 81.6 mm bore and 66.9 mm stroke.  
151 The geometrical compression ratio was set to 11.8:1. Commercial UK gasoline (RON 95) was  
152 directly injected into the cylinder at 15.0±0.5 MPa and 293±5 K by a double-slit Denso injector side  
153 mounted between the intake ports. The fuel mass flow rate was measured by an Endress+Hauser  
154 Coriolis Promass 83A with a maximum error of ±0.2%. Spark timing, injection timing and duration,  
155 and valve events were managed by a Ricardo rCube unit, while the exhaust throttle was manually  
156 operated. A transient dynamometer enabled constant speed tests at 800 and 2000±5 rpm, while a  
157 LeineLinde incremental encoder with 720 pulses per revolution was employed to record the crank

158 position. Intake and exhaust valve positions were recorded by four Lord DVRT linear variable  
159 displacement transducers (LVDT) with a resolution better than 6  $\mu\text{m}$  and repeatability of  $\pm 1 \mu\text{m}$ .  
160 The signals from the LVDTs were pre-processed by a Lord Multichannel conditioner at 20 kHz,  
161 with a maximum error of 1% due to signal linearization. Valve opening and closing times were  
162 flagged at 0.7 mm of valve lift.

163 The boosted intake air necessary to scavenge the burned gases during the valve overlap  
164 was supplied by an AVL 515 compressor unit at a constant pressure of  $135 \pm 4 \text{ kPa}$  and  
165 temperature of  $300 \pm 5 \text{ K}$ . The air mass flow rate was measured by a Hasting HFM-200 laminar flow  
166 meter with a maximum error of 1%. Intake and exhaust pressures were acquired by two piezo-  
167 resistive transducers installed in the intake plenum (4007BA20F) and exhaust port (4007BA5F),  
168 with a maximum error of  $\pm 0.1\%$  each. At the same points the average temperatures were  
169 measured by K-type thermocouples with  $\pm 1\%$  accuracy. A Kistler 6061B piezo-electric transducer  
170 was used to monitor the in-cylinder pressure with maximum error of  $\pm 0.5\%$ . Engine oil and coolant  
171 temperatures were kept at  $353 \pm 3 \text{ K}$ . The exhaust oxygen concentration was measured by a Horiba  
172 MEXA 7170DEGR using a paramagnetic sensor, with an error smaller than 2%. A National  
173 Instruments 6353 USB X card was used for data acquisition purposes. The location of the  
174 instruments can be found in Figure 2, as well as the temperature and pressure measurement  
175 points labelled as "T" and "P", respectively.

176  
177 Figure 2 – Test cell facilities.

179 The air trapping efficiency ( $TE$ ) is defined as the ratio of in-cylinder trapped air mass  
 180 ( $m_{TRAP}$ ) at intake or exhaust valve closing (whichever later) to the total air mass supplied every  
 181 engine cycle ( $m_{TOT}$ ). It was calculated based on the exhaust air/fuel ratio ( $AFR_{EXH}$ ), exhaust  
 182 oxygen concentration ( $[O_2]_{EXH}$ ) and ambient oxygen concentration ( $[O_2]_{AMB}$ ), considered 209500  
 183 ppm, as presented in Equation (1) from [44].

$$TE = \frac{m_{TRAP}}{m_{TOT}} = 1 - \frac{(1 + AFR_{EXH})[O_2]_{EXH}}{AFR_{EXH}[O_2]_{AMB}} \quad (1)$$

184 The in-cylinder lambda ( $\lambda_{CYL}$ ) differed from the exhaust lambda ( $\lambda_{EXH}$ ) as a result of air  
 185 short-circuiting from the intake to the exhaust during the scavenging process. In all tests  $\lambda_{EXH}$  was  
 186 found greater than  $\lambda_{CYL}$  and always above the unit, which is normally used in four-stroke engines  
 187 for aftertreatment purposes. The exhaust lambda, calculated from air and fuel flow rate  
 188 measurements, was multiplied by the air trapping efficiency so the in-cylinder lambda could be  
 189 obtained as presented in Equation (2).

$$\lambda_{CYL} = \frac{AFR_{CYL}}{AFR_{STOICH}} = \lambda_{EXH} TE = \frac{AFR_{EXH}}{AFR_{STOICH}} \left( 1 - \frac{(1 + AFR_{EXH})[O_2]_{EXH}}{AFR_{EXH}[O_2]_{AMB}} \right) \quad (2)$$

190 To ensure a minimum amount of free oxygen in the exhaust, and therefore avoid under  
 191 prediction of air trapping efficiency, the in-cylinder lambda was kept in the range 0.93 - 0.95 at all  
 192 tests. The fuel-rich in-cylinder mixture was obtained by measuring and processing on real-time air  
 193 and fuel flow rates alongside the exhaust oxygen concentration. This calculation method based on  
 194 exhaust oxygen detection is known to provide excellent results under homogeneous air-fuel  
 195 charging processes, such as through port fuel injection systems [6]. However, the use of direct fuel  
 196 injection induced a certain level of fuel stratification and therefore some inaccuracies may have  
 197 taken place during the measurements. Considering this, the start of injection (SOI) was set as  
 198 early as possible to improve the charge homogeneity but respecting intake valve closing (IVC) and  
 199 exhaust valve closing (EVC) to avoid fuel short-circuiting. Furthermore, the engine speeds tested  
 200 i.e. 800 rpm and 2000 rpm were low in comparison to small/mid-sized two-stroke engines. This

201 enabled a longer charge preparation, so better fuel vaporisation and mixing with air and residual  
202 gas could be obtained.

203 The scavenge ratio ( $SR$ ) is defined as the ratio of total inlet air mass to the in-cylinder  
204 reference mass at intake conditions. This reference mass was calculated from the in-cylinder  
205 volume ( $V_{CYL}$ ) at IVC or EVC, whichever later, and the intake air density ( $\rho_{INT}$ ). The clearance  
206 volume ( $V_{CLR}$ ) was also considered as seen in Equation (3) from [6].

$$SR = \frac{m_{TOT}}{(V_{CYL} + V_{CLR})\rho_{INT}} \quad (3)$$

207 The charging efficiency ( $CE$ ) was used to quantify how efficiently the cylinder was filled with  
208 air. It expresses the ratio between in-cylinder trapped air mass at IVC or EVC (whichever later)  
209 and the in-cylinder reference mass at intake conditions. Therefore, it results from the product  
210 between scavenge ratio and air trapping efficiency as shown in Equation (4).

$$CE = \frac{m_{TRAP}}{(V_{CYL} + V_{CLR})\rho_{INT}} = SR * TE \quad \therefore \quad RGF \cong 1 - CE \quad (4)$$

211 Under idealized flow conditions i.e. the scavenging process occurring at isobaric and  
212 isothermal conditions, burned and unburned zones may assume identical densities [6]. Thus, the  
213 residual gas fraction (RGF) can be roughly estimated from the difference between the charging  
214 efficiency and the unit.

215 The effective expansion ratio (EER) was determined by the in-cylinder volume at exhaust  
216 valve opening (EVO) or intake valve opening (IVO), whichever earlier. Similarly, the effective  
217 compression ratio (ECR) was calculated at EVC or IVC, whichever later, as presented in Equation  
218 (5).

$$EER \text{ and } ECR = \frac{V_{CYL} + V_{CLR}}{V_{CLR}} \quad (5)$$

219 In real world conditions part of the output power of the two-stroke poppet valve engine  
220 would be delivered to an external air compressor. Therefore, this supercharger power requirement  
221 ( $\dot{W}_C$ ) was estimated based on the first and second laws of thermodynamics in a total to static  
222 compression process shown in Equation (6) from [45].

$$\dot{W}_C = \dot{m}C_pT_{AMB} \left( \left( \frac{P_{INT}}{P_{AMB}} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right) \frac{1}{\eta_C\eta_M} \quad (6)$$

223 where  $\dot{m}$  is the air mass flow rate,  $C_p$  is the specific heat of air at constant pressure (considered  
 224 1.004 kJ/kg.K),  $T_{AMB}$  is the ambient temperature,  $P_{INT}$  is the engine intake pressure,  $P_{AMB}$  is the  
 225 ambient pressure,  $\gamma$  is the ratio of specific heats (considered 1.40),  $\eta_C$  is the compressor isentropic  
 226 efficiency (considered 0.70), and  $\eta_M$  is the compressor mechanical efficiency (considered 0.85). It  
 227 is known that these efficiencies, particularly the isentropic efficiency, largely change with pressure  
 228 ratio and air flow rate. Nevertheless, these values were estimated based on contemporary  
 229 mechanically driven radial flow compressors [46], which are generally more efficient than roots  
 230 type superchargers.

231 Four-stroke engines have one firing cycle every two revolutions and hence their IMEP  
 232 values are twice as high as those found in two-stroke engines of the same displacement and  
 233 running at the same speed. Therefore, to avoid misunderstandings in the loads achieved in the  
 234 two-stroke cycle, the indicated specific torque ( $T_{is}$ ) was employed as seen in Equation (7).

$$T_{is} = \eta_i m_{TRAP} \left( \frac{LHV}{2\pi V_{CYL} AFR_{CYL}} \right) \quad (7)$$

235 where  $LHV$  is the lower heating value of the fuel and  $\eta_i$  is the indicated efficiency.

### 236 2.3 Evaluation of valve timings

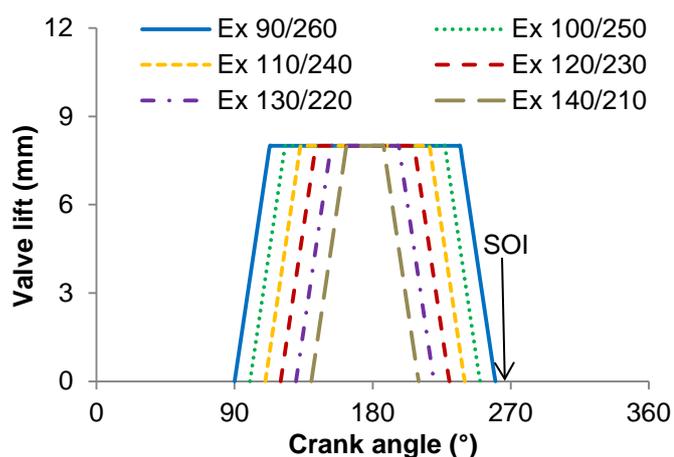

237 Intake and exhaust valve operations were centred at 185° and 175° of crank angle (CA)  
 238 after top dead centre (ATDC), respectively, based on previous experimental observation [47].  
 239 Valve opening durations were independently varied from 50° CA to 150° CA (intake) and from 70°  
 240 CA to 170° CA (exhaust). An increment of 20° CA was used between each testing point as shown  
 241 in Figure 3 and Figure 4 for intake and exhaust valves, respectively. While the exhaust valve  
 242 opening duration was fixed at a constant value, the intake valve timing was varied. After this, the  
 243 exhaust valve timing was varied 20° CA and another set of intake durations was evaluated. The  
 244 procedure was repeated until the peak torque was achieved at 800 rpm and 2000 rpm at both  
 245 intake and exhaust duration sweeps. The valve lifts were set to 8 mm in all cases. The  
 246 nomenclature used from Figure 7 to Figure 13 consists of intake and exhaust valve opening and

247 closing times, in this sequence. For instance, in the case “In 130/240, Ex 120/230” the intake  
248 valves opened at 130° CA ATDC and closed at 240° CA ATDC, while the exhaust valves opened  
249 at 120° CA ATDC and closed at 230° CA ATDC.

250 In total, 25 different valve timings were experimentally assessed. To avoid the interference  
251 of the air-fuel mixing process on the results, the SOI was set to 260° CA ATDC, which was the  
252 latest IVC/EVC timing studied. In this case no fuel short-circuiting, as well as its backflow to the  
253 intake port, were expected to happen so the fuel trapping efficiency could be maximised. Knocking  
254 combustion limited the spark timing advance in all cases at both engine speeds. In other words,  
255 the earliest ignition timing towards the minimum spark advance for best torque (MBT) was applied.

256

257 Figure 3 – Intake valve opening duration sweep.

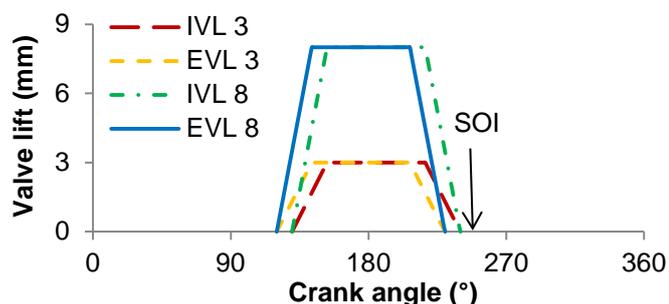

258

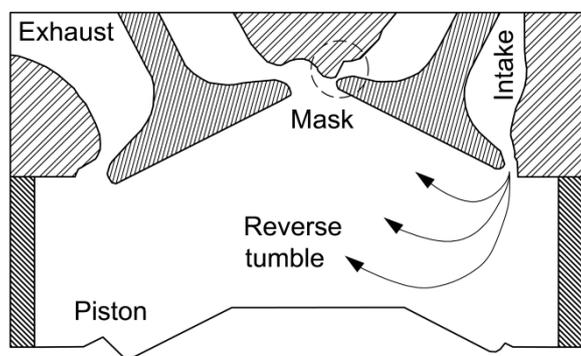

259 Figure 4 – Exhaust valve opening duration sweep.

260 2.4 Evaluation of valve lift and exhaust backpressure

261 Intake and exhaust valves were independently evaluated at 3 mm and 8 mm of lift as seen  
262 in Figure 5. The valve timing chosen in this case was that which presented appreciable output  
263 torque at 800 rpm and 2000 rpm, simultaneously, in the valve timing assessment. The 3 mm of  
264 valve lift matched the cylinder head mask height around the intake valves as shown in Figure 6.  
265 On the other hand, the 8 mm of lift represented the maximum value achieved by the  
266 electrohydraulic valve train unit and uncovered the head mask in 5 mm. It was also close to the  
267 dimensionless valve lift of 0.3 L/D (where “L” is the valve lift and “D” is the valve diameter). This is  
268 accepted as a limiting value beyond which the discharge coefficient presents small changes [45].  
269 Therefore, the influence of the cylinder head mask on gas exchanging and engine performance  
270 could be investigated. The nomenclature used from Figure 14 to Figure 20 consists of intake valve  
271 lift (IVL) followed by exhaust valve lift (EVL), with the related numbers indicating the valve lifts in  
272 millimetres.

273  
274 Figure 5 – Intake and exhaust valve lift sweeps.

275  
276 Figure 6 – Masked cylinder head and arrangement of intake/exhaust ports. Adapted from [47].

277 For each of the 12 different intake/exhaust valve lifts examined, three exhaust  
278 backpressures (BP) i.e. ~104 kPa, 110 kPa and 120 kPa were studied. The lowest exhaust

279 backpressure tested was that of typical silencer and pipes, which remained between 103 kPa and  
280 104 kPa depending on the valve lift used. For instance, the case “IVL 3, EVL 8, BP 110” used 3  
281 mm and 8 mm of lift in the intake and exhaust valves, respectively, with an exhaust backpressure  
282 of 110 kPa. The SOI was advanced towards IVC (240° CA ATDC) to enhance the mixture  
283 homogeneity. In all cases the spark timing advance was limited by knocking combustion and MBT  
284 could not be achieved.

### 285 **3. Results and discussion**

286 The following results were averaged over 200 consecutive cycles and plotted as a function  
287 of valve timing, lift and exhaust backpressure at 800 rpm and 2000 rpm. In the valve opening  
288 duration plots (Figure 7 to Figure 13) the dashed lines represent the trend of the exhaust valve  
289 sweep. Each of the six plots in the figures represents an individual intake valve sweep at constant  
290 exhaust valve timings. The exhaust valve opening duration decreases from the left to the right in  
291 each figure, while the intake opening duration decreases from the left to the right in each plot. In  
292 the valve lift and exhaust backpressure results (Figure 14 to Figure 20), the dashed lines represent  
293 the exhaust backpressure sweeps increasing from the left to the right. Each of the three plots  
294 denotes the intake and exhaust valve lift sweeps at a constant exhaust backpressure.

#### 295 3.1 Assessment of different valve timings

296 For all the 25 valve timings tested, the indicated specific torque was found in the range from  
297 76 Nm/dm<sup>3</sup> to 185 Nm/dm<sup>3</sup>. In values of IMEP this load spanned from 0.48 MPa to 1.16 MPa. This  
298 means that a four-stroke engine of the same swept volume would need to be operated from 0.96  
299 MPa to 2.32 MPa to deliver the same torque at the same speed.

300 The indicated specific torque presented in Equation (7) is a function of indicated efficiency,  
301 charging and fuelling characteristics. Values between parentheses in that equation i.e. lower  
302 heating value of the fuel, exhaust air/fuel ratio and cylinder volume were kept constant during the  
303 tests. Meanwhile, the in-cylinder trapped air mass corresponded to the combination of air trapping  
304 efficiency and scavenge ratio, which is therefore the charging efficiency defined in Equation (4).  
305 Finally, the indicated efficiency was mostly a function of EER and ECR presented in Figure 8. The

306 influence of combustion parameters i.e. combustion duration and phasing, were not independently  
307 considered as they were linked to ECR and scavenging process at the constant air/fuel ratio set.

308 At 800 rpm the specific torque increased at shorter intake/exhaust valve opening durations  
309 until "intake valve sweep 5", as seen from the left to the right side along the X-axis in Figure 7. This  
310 was a result of increasing EER and ECR at more retarded EVO/IVO and more advanced EVC/IVC,  
311 respectively. At extremely short valve durations, although, EER and ECR effects were offset by the  
312 shorter time available for scavenging and a large amount of residual gas was trapped. The greater  
313 RGF caused the in-cylinder charge temperature to increase and more retarded spark timings were  
314 used to avoid knocking combustion, therefore reducing the output torque. The inflexion point was  
315 found around 90° CA of intake/exhaust valve duration (In 140/230, Ex 130/220). Therefore, other  
316 than this operating point the engine torque deteriorated with either longer or shorter valve opening  
317 durations. In contrast, at 2000 rpm longer exhaust durations were made necessary to allow an  
318 effective scavenging process, as the time available to it was reduced. Besides the greater frictional  
319 flow losses at 2000 rpm, the scavenging process also suffered from the smaller effective flow area  
320 resulted from the actuation speed of the electrohydraulic valve train. The valve opening and  
321 closing durations were constant on a time basis and not on a crank angle basis as in conventional  
322 engines. Therefore, the higher the engine speed the less steep the opening/closing slopes  
323 became, which reduced the effective flow area. Excessively long exhaust valve opening durations  
324 also decreased the specific torque as seen in intake valve sweeps 1 and 2 (first and second plots  
325 in Figure 7). The lower ECR and EER (Figure 8) reduced the specific torque in these cases. The  
326 torque could be only partially recovered by higher charging efficiencies at longer intake valve  
327 opening durations (e.g. "In 110/260, Ex 90/260" and "In 120/250, Ex 100/250") as seen in Figure 9.

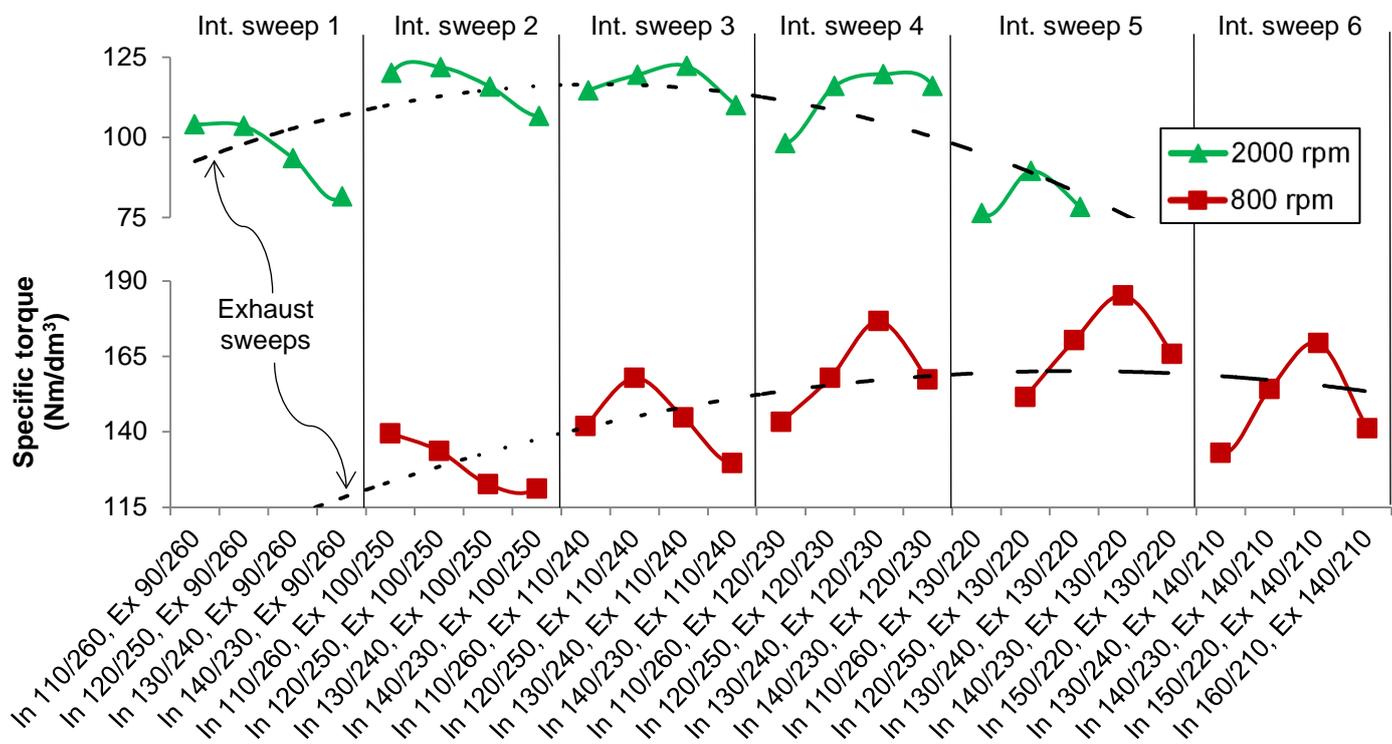

Figure 7 – Indicated specific torque results for the valve timing sweep.

As exhaust valve opening was retarded towards BDC, the EER increased and a higher torque was expected. However, as the in-cylinder pressure decreased close to BDC, the pressure ratio across the exhaust valves also dropped at EVO and the scavenging process was hindered by the weak exhaust blowdown. The highest specific torque of 185 Nm/dm<sup>3</sup> was achieved at 800 rpm with the valve timing “In 140/230, Ex 130/220”. At 2000 rpm the maximum torque of 122 Nm/dm<sup>3</sup> was reached with “In 130/240, Ex 110/240”. At lower speeds the longer time available for gas exchange enabled earlier EVC and hence a reasonable ECR of 10.3:1. Meanwhile, at 2000 rpm the time available for scavenging deteriorated and EVC was delayed, which reduced the ECR to about 8.8:1. This reduction in ECR is not desirable and the higher the speed the poppet valve engine is to achieve, the lower it will be due to the increased valve opening duration required. For the sake of comparison, mid/high-speed ported two-stroke engines typically operate with a constant ECR of about 6 to 7:1 [22].

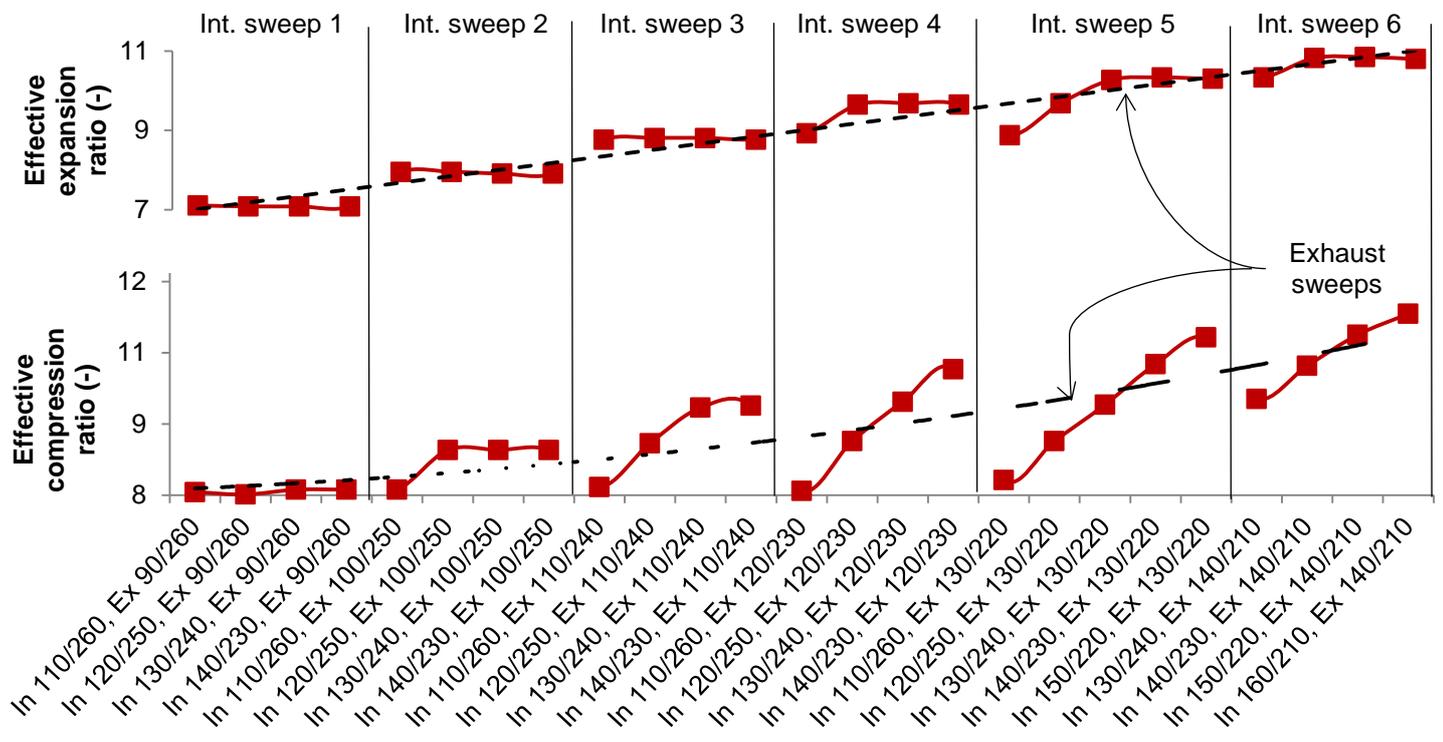

Figure 8 – Effective expansion and compression ratio results for the valve timing sweep.

The specific torque (Figure 7) and charging efficiency (Figure 9) results suggested that the shorter the exhaust duration, the shorter should be the intake duration as well. This effect was observed by the moving “peak” in the curves at both engine speeds tested, although at 800 rpm it was more pronounced. At 800 rpm and in the second intake valve sweep, the peak torque was near the first point investigated of “In 110/260, Ex 100/250”. As the exhaust valve duration decreased, the peak torque moved towards shorter intake durations as seen in the third intake valve sweep in the case “In 120/250, Ex 110/240”. Between these two cases the exhaust duration was shortened by 20° CA, while the intake duration was reduced by the same amount to produce the maximum torque. The common characteristic amongst all peak torque points found at 800 rpm was that EVO took place 10° CA before IVO. This ensured an effective exhaust blowdown phase before intake valve opening. When the intake valve opened before this 10° CA limit, intake backflow occurred and the charge purity decreased. Conversely, when IVO took place long after EVO the exhaust blowdown weakened and the pressure ratio across the exhaust valves dropped excessively until the scavenging process could start.

Another common feature amongst the highest torque points at 800 rpm was that IVC took place 10° CA after EVC. This configuration increased the charging efficiency (Figure 9) by

360 providing a “supercharging effect” at the onset of compression [22]. In other words, at EVC the in-  
361 cylinder pressure was somewhat above exhaust pressure but below inlet pressure due to the  
362 valves restriction (in the absence of wave tuning). Therefore, by closing the intake valves after the  
363 exhaust valves more time was allowed for the in-cylinder pressure to increase towards the intake  
364 pressure, which was always higher than the exhaust pressure (in average). Some degree of ram  
365 effect was also expected to increase the charging efficiency based on the inertia of the intake air.  
366 Furthermore, the earlier EVC avoided the fresh charge from exiting the cylinder through the  
367 exhaust valves at such low speed. In conventional two-stroke engines, where the symmetric port  
368 arrangement makes it prohibitive to close the intake port(s) after the exhaust port(s), some of the  
369 fresh charge leaves the cylinder during the scavenging process. This shortcoming is often  
370 improved by exhaust timing valves at low engine speeds [40] and by wave propagation in tuned  
371 exhaust pipes [6] at high engine speeds. Nevertheless, when IVC took place long after EVC  
372 backflow occurred as the in-cylinder pressure became higher than the inlet pressure at IVC. The  
373 case “In 110/260, Ex 110/240” was such an example where the backflow reduced charging  
374 efficiency and consequently the output torque. At 2000 rpm the peak charging efficiency and  
375 torque were obtained when both IVC and EVC occurred at the same time, which indicated the  
376 need for longer intake/exhaust valve opening durations at higher engine speeds to improve the  
377 scavenging. At engine speeds above 2000 rpm one would expect the peak torque to occur at an  
378 EVC beyond IVC, which is the case of conventional ported two-stroke engines.

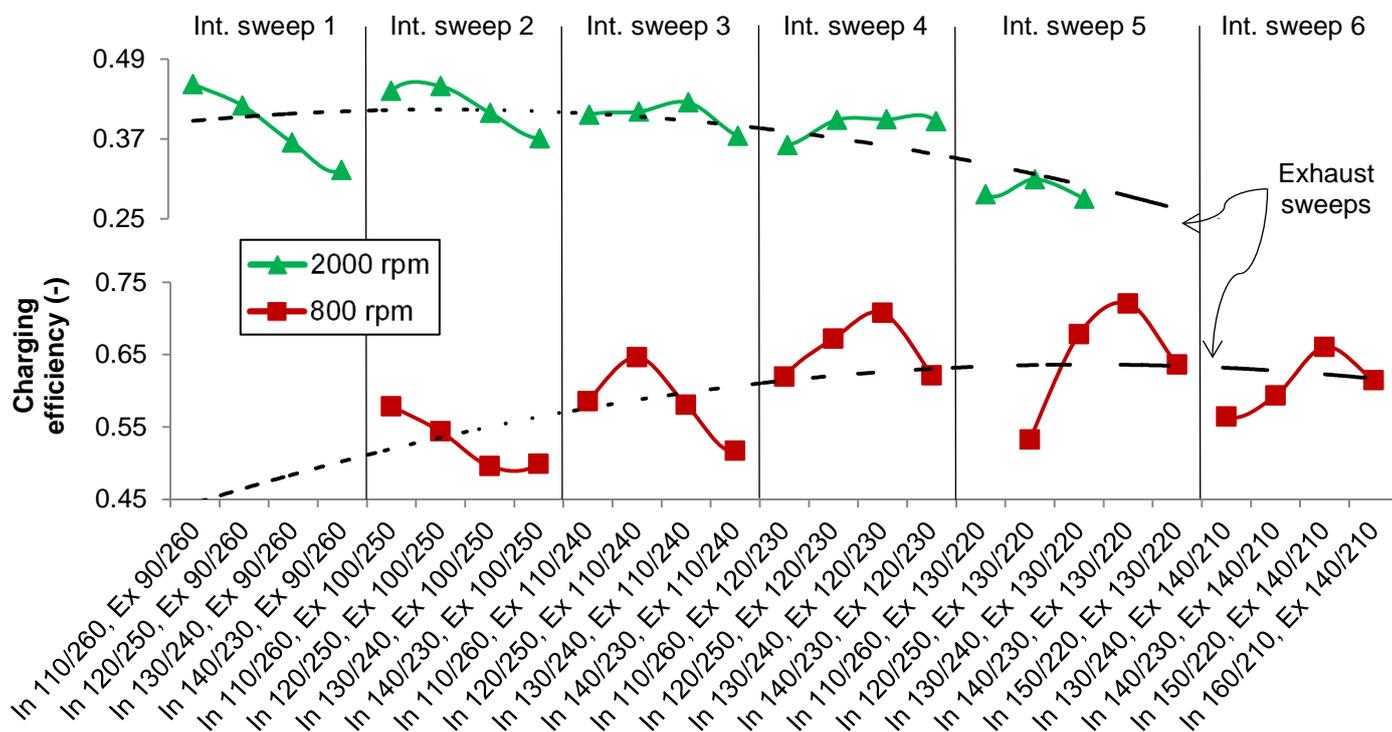

Figure 9 – Charging efficiency results for the valve timing sweep.

From Figure 7 and Figure 9 it is evident the strong correlation between charging efficiency and output torque as also reported in the literature [48]. An interesting event seen in Figure 9 was the reduction in charging efficiency when intake and exhaust valves opened at the same time as in the cases “In 120/250, Ex 120/230” and “In 130/240, Ex 130/220”. Both cases preceded the highest charging efficiencies points at 800 rpm and the reduction in torque by opening all the valves at the same time was around 10%. In these cases not only the effectiveness of the blowdown was reduced but a higher in-cylinder pressure at IVO also hindered the initial phase of the scavenging process. At 2000 rpm the difference in charging efficiency between the highest torque cases and those when intake/exhaust valves were opened at the same time decreased to about 4%. This behaviour suggested that the exhaust blowdown phase was not very critical in the scavenging process at higher speeds under lower values of scavenge ratio as observed in Figure 10. Furthermore, the first portion of air entering the cylinder is usually mixed with burned gases and expelled in the exhaust [22]. Thus, the air contamination in the intake ports when IVO and EVO took place together had little effect on the purity of the trapped charge, as the cylinder was actually filled with a later portion of the inducted air at the onset of compression.

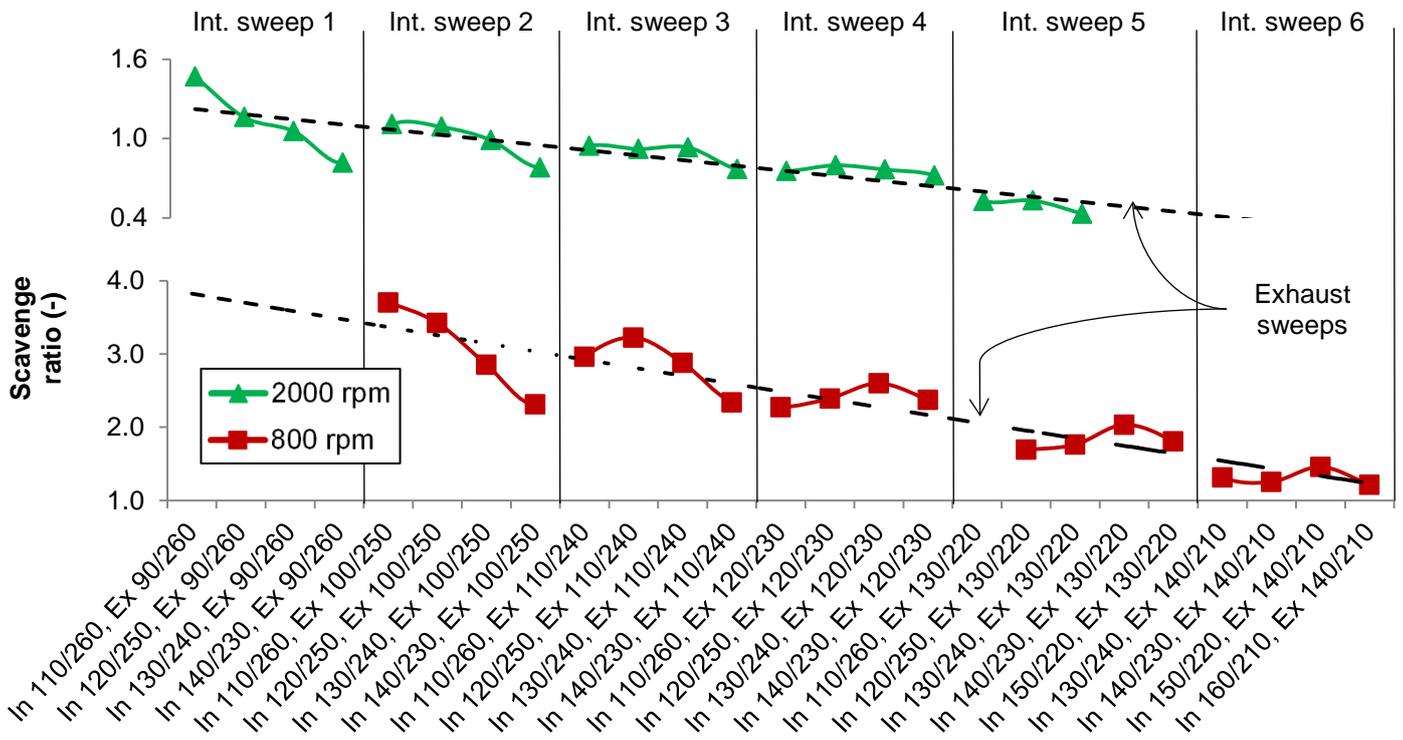

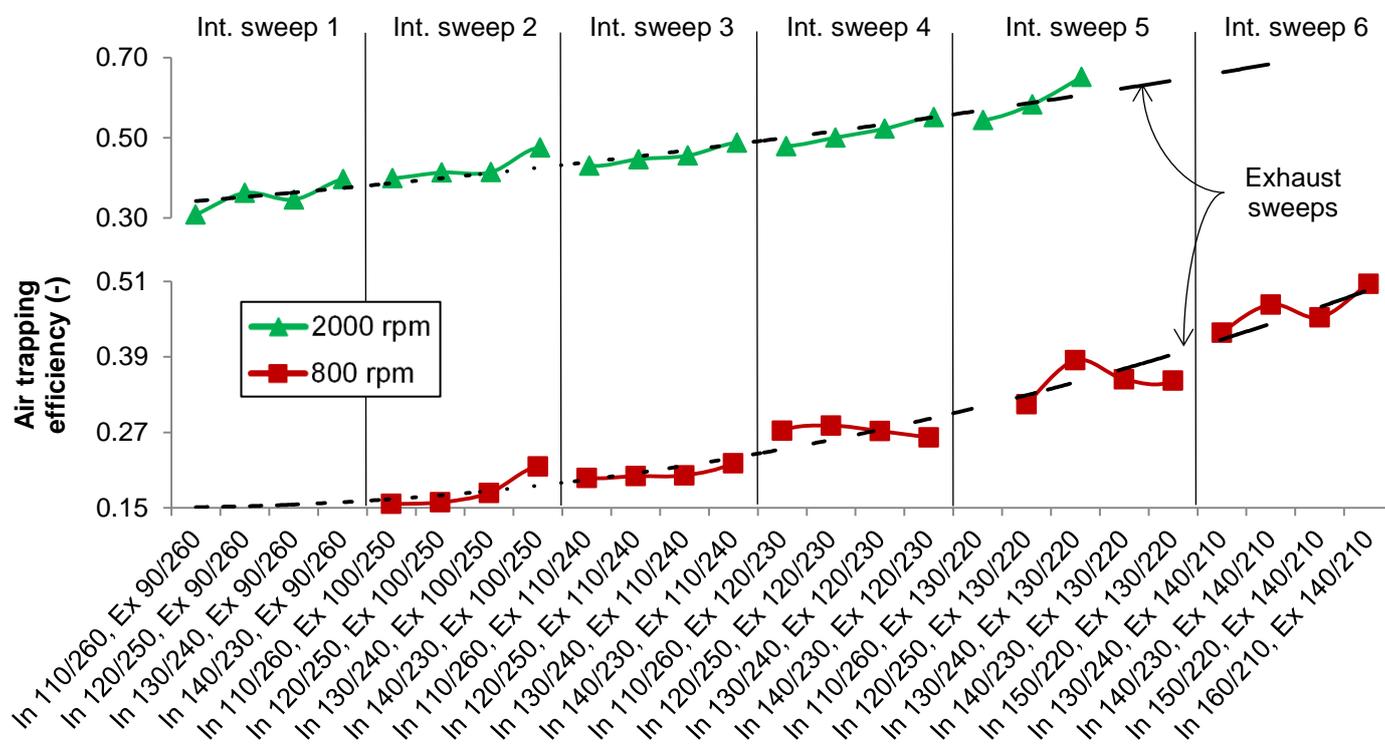

Figure 10 – Scavenge ratio results for the valve timing sweep.

The scavenge ratio seen in Figure 10 increased linearly with exhaust valve opening duration. At 2000 rpm the engine operation was not possible at intake/exhaust valve opening durations below 110°/90° CA, respectively, as a result of scavenge ratios as low as 0.43 and air trapping efficiencies of up to 0.65. The large RGF in these cases elevated the in-cylinder charge temperature and required the spark timing to be retarded to avoid knocking combustion. The exceedingly retarded values of ignition timing resulted in unstable combustion and misfire, so these operating points were disregarded.

From the exhaust sweep at 2000 rpm it was clear that even with intake and exhaust durations as long as 150° CA and 170° CA, respectively, the charging efficiency (Figure 9) could not increase above 0.45. The same impossibility of improving the charging process was found at 800 rpm as the intake and exhaust valve durations increased beyond 110° CA. At both speeds there was plenty of air supply as seen by the high scavenge ratio values in Figure 10. For the sake of comparison, at 800 rpm the scavenge ratio reached an overall maximum of 3.71, while in ported two-stroke engines this value rarely overtakes 1.5 at full load [6]. Under these circumstances the excess of air supplied was not efficiently scavenging the burned gases. Instead, it was actually being lost to the exhaust system. This fact was confirmed by the low values of air trapping

414 efficiency found for these valve opening durations, particularly at 800 rpm. Figure 11 presents the  
 415 clear correlation between air trapping efficiency and exhaust valve sweeps at both engine speeds,  
 416 although at 2000 rpm it was more evident. Comparatively, the intake valve sweeps had a less  
 417 pronounced effect on air trapping efficiency.

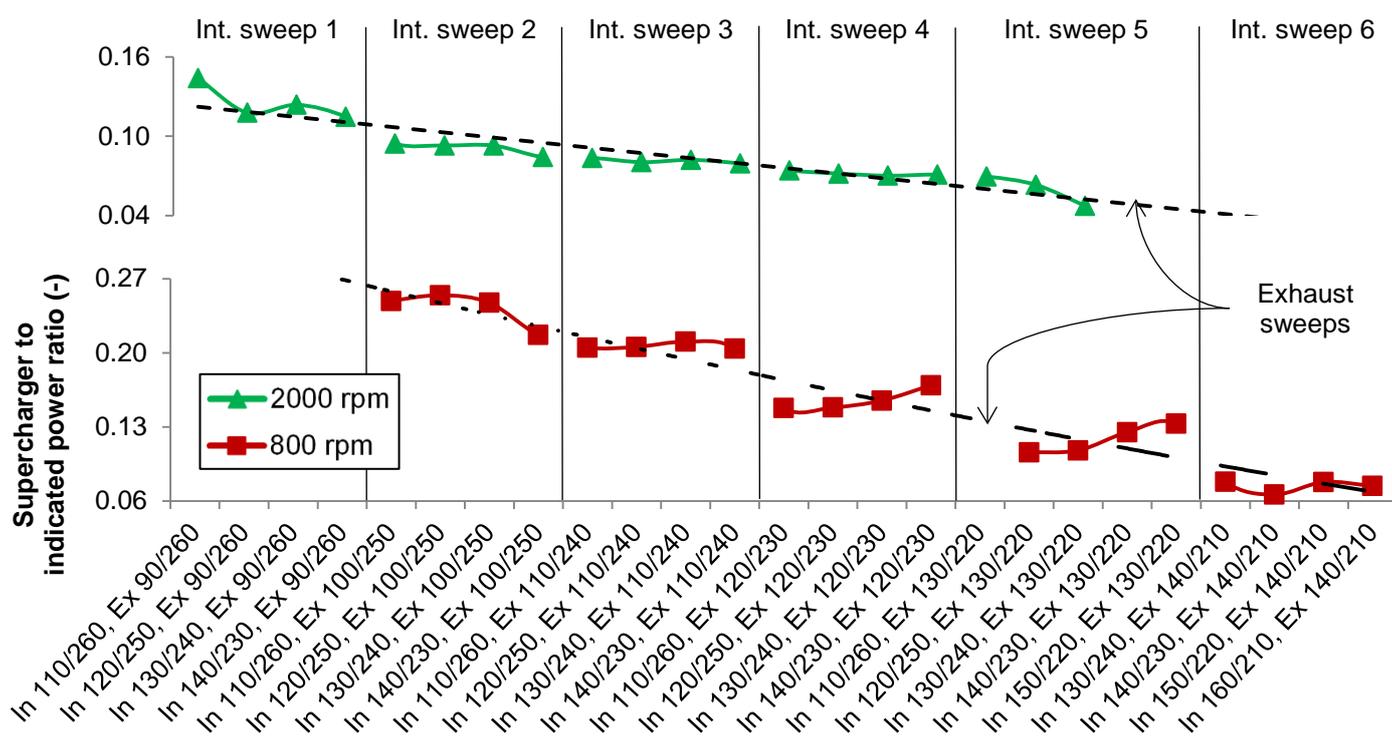

418  
 419 Figure 11 – Air trapping efficiency results for the valve timing sweep.

420 It is important to clarify that not all of the air present in the exhaust resulted from air short-  
 421 circuiting, as assessed via air trapping efficiency calculation at fuel-rich in-cylinder conditions. Part  
 422 of the intake charge mixed with the burned gases during the mixing-scavenging process, so it was  
 423 not possible to distinguish the portions of short-circuited air from those mixed during the  
 424 scavenging. The mixing-scavenging is still a form of scavenging, although it is not as efficient as  
 425 perfect displacement. It is still better than pure short-circuiting, when the burned gas is not  
 426 displaced from the combustion chamber.

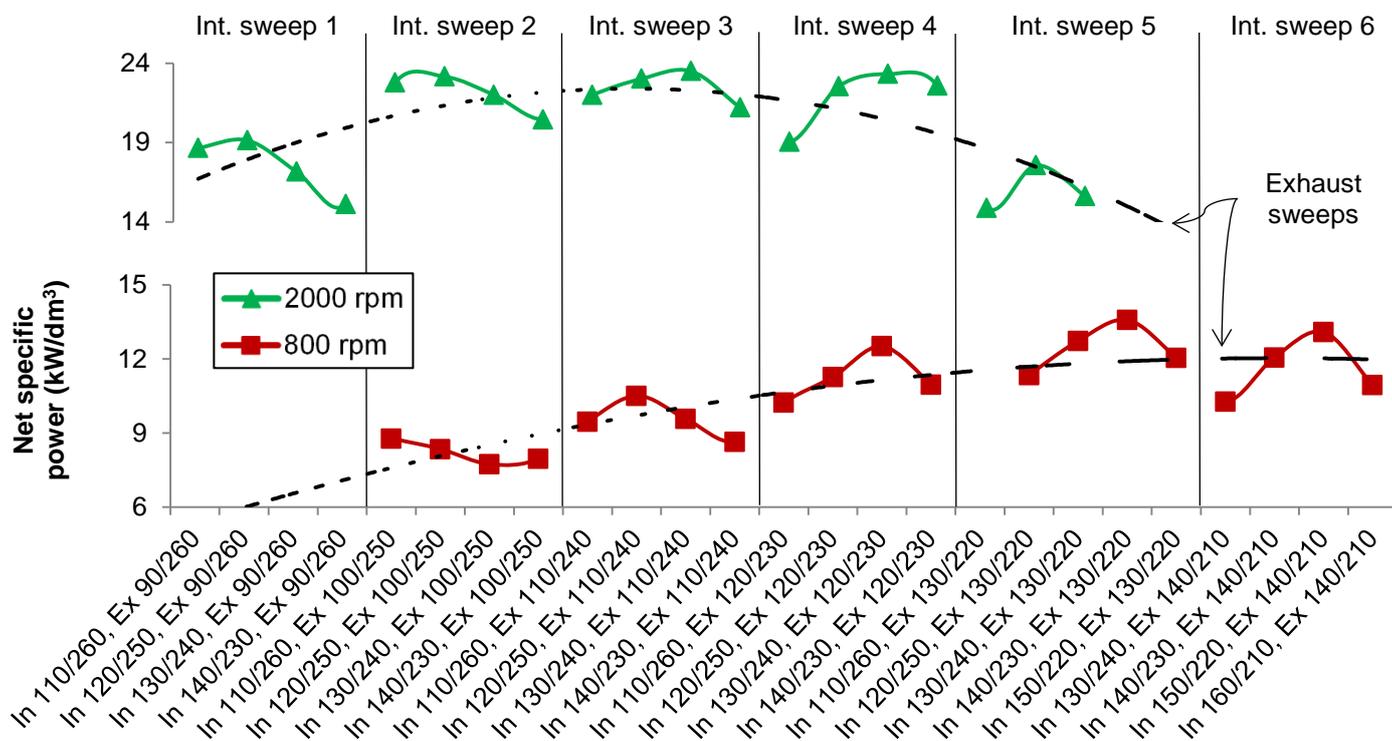

427 Although the output torque was directly linked to the charging efficiency, high values of air  
 428 trapping efficiency were also desirable to ensure that the fresh charge was not lost in the exhaust.  
 429 As seen in Equation (4), charging efficiency is the product of air trapping efficiency and scavenge  
 430 ratio. Thus, a higher output torque could not be achieved by only increasing the scavenge ratio at  
 431 low values of trapped air mass. This was the case of very long exhaust valve durations, so the

432 power consumed by the supercharger was considerably large as shown by its ratio to the indicated  
433 power in Figure 12.

434  
435 Figure 12 – Ratio of supercharger power requirement to engine indicated power for the valve  
436 timing sweep.

437 As the exhaust valve opening duration increased (right to left in plots), the air trapping  
438 efficiency dropped and a larger fraction of supplied air was lost in the exhaust. This waste of  
439 energy, particularly visible at 800 rpm, explained the greater values of supercharger power  
440 consumption on the left end intake sweeps (Figure 12). At both engine speeds the trend for this  
441 power ratio was considerably similar to the exhaust sweeps, while intake valve timing played again  
442 a less important role. Due to the lower scavenge ratio, higher air trapping efficiency, and greater  
443 indicated power at 2000 rpm, the fraction of power consumed by the supercharger remained  
444 between 5% and 14%. At 800 rpm the supercharger to indicated power ratio varied from 7% to  
445 25%. Figure 13 reveals the best intake/exhaust valve timings to produce the highest possible net  
446 power, which was calculated by the subtraction of supercharger power consumption from the  
447 indicated power.

448

449

Figure 13 – Net indicated specific power considering the supercharger power consumption for the valve timing sweep.

450

451

At 800 rpm the valve timing “In 140/230, Ex 130/220” made it possible to achieve 13.6 kW/dm<sup>3</sup>. The cases “In 150/220, Ex 140/210” and “In 130/240, Ex 120/230” reached 4% and 8% less power, respectively. At 2000 rpm nearly the same net specific power was obtained at the three “peaks” in intake sweeps 2, 3 and 4. A value of 23.3 KW/dm<sup>3</sup> ( $\pm 2\%$ ) was acquired at “In 120/250, Ex 100/250”, “In 130/240, Ex 110/240” and “In 130/240, Ex 120/230”. This result demonstrated a certain flexibility of the engine for different valve configurations at higher speeds.

452

Aiming at a single valve timing to be tested with different valve lifts and exhaust backpressures, the case “In 130/240, Ex 120/230” was chosen for its reasonable performance at both speeds. At 800 rpm this case represented a reduction of about 8% in the net specific power compared to the best case, although at 2000 rpm the difference was irrelevant.

453

454

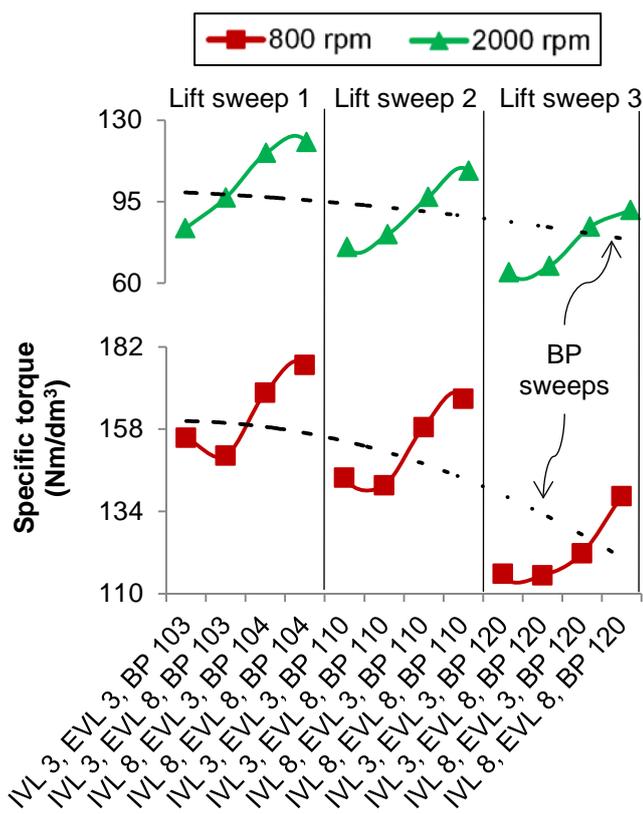

### 3.2 Assessment of different valve lifts and exhaust backpressures

455

From Figure 14 it is noticeable that any reduction of intake and exhaust valve lifts from the maximum value of 8 mm resulted in poorer torque at both speeds and any exhaust backpressure. The results suggested that the intake mask affected more the scavenging process than the flow

456

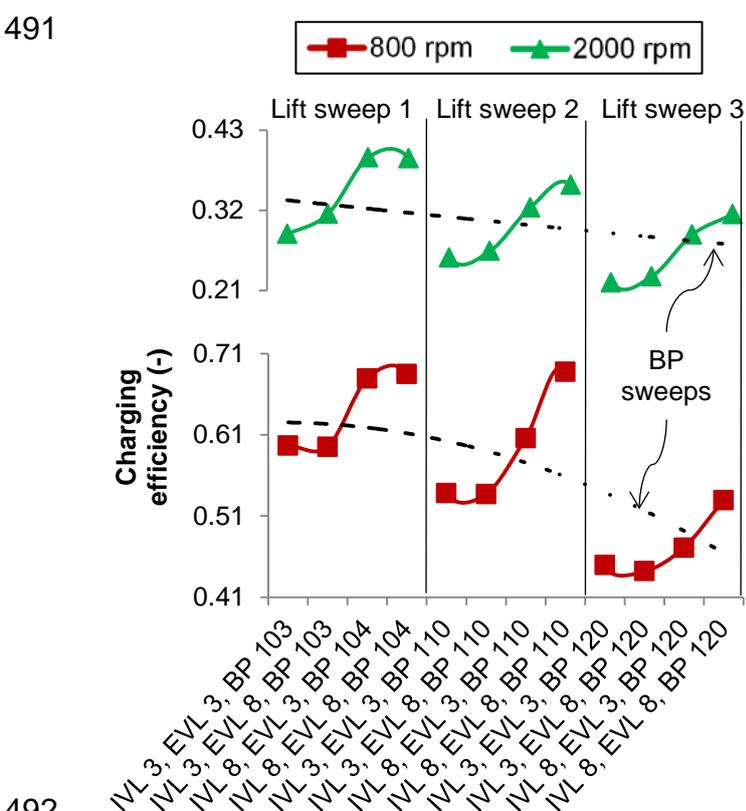

465 restriction resulted from lower exhaust valve lift. While the masked region around the intake valves  
 466 was supposed to increase air trapping efficiency through lower air short-circuiting, the decrease in  
 467 charging efficiency was more pronounced (Figure 15) and hence the torque deteriorated. This fact  
 468 was further evidenced by the gain in specific torque and charging efficiency when comparing the  
 469 three last cases in the first lift sweep (Lift sweep 1). When IVL was increased from 3 mm to 8 mm  
 470 and EVL reduced from 8 mm to 3 mm, the output torque increased by 20% at 2000 rpm. However,  
 471 when EVL was raised from 3 mm to 8 mm at a constant IVL of 8 mm, the improvement in torque  
 472 was around 4%. It is known that the scavenging process in ported two-stroke engines is strongly  
 473 dependent on the exhaust port details. For the same reason, the two-stroke poppet valve engine  
 474 used in this research has exhaust valves larger than intake valves (30 mm against 28 mm).  
 475 However, there was no performance gain by fully opening the exhaust valves if the intake flow was  
 476 restricted at 3 mm of valve lift as in the cases “IVL 3, EVL 8”.

478  
 479 Figure 14 – Indicated specific torque results for the valve lift and exhaust backpressure sweeps.

480 The indicated specific torque trend at 800 rpm was not as linear as that at 2000 rpm  
 481 because the cases with 3 mm of IVL and 8 mm of EVL presented poorer performance than those  
 482 with 3 mm of IVL and EVL. This fact only happened at 800 rpm and was attributed to lower in-

483 cylinder trapped air mass at the onset of compression. Despite the fact that IVC occurred after  
 484 EVC in all cases, the greater exhaust valve area at 8 mm of lift allowed more fresh charge to leave  
 485 the cylinder at such low speed. The low IVL imposed a greater restriction to the intake air flow and  
 486 the incoming charge could not compensate for the lack of filling in only 10° CA between EVC and  
 487 IVC. On the other hand, in the cases with IVL and EVL of 3 mm a larger in-cylinder trapped air  
 488 mass was obtained thanks to the greater restriction imposed by the lower EVL. As the exhaust  
 489 backpressure increased, more charge was trapped and the difference between 3 mm and 8 mm of  
 490 EVL (at a constant IVL of 3 mm) vanished as supposed.

492  
 493 Figure 15 – Charging efficiency results for the valve lift and exhaust backpressure sweeps.

494 As the exhaust backpressure increased (from the left to the right in the plots), the output  
 495 torque gradually deteriorated at both engine speeds. The increase in exhaust backpressure also  
 496 hindered the effect of lower valve lifts at both speeds due to the reduction in pressure ratio across  
 497 the valves. This was evidenced by the less steep curves in the specific torque and charging  
 498 efficiency plots in Figure 14 and Figure 15, respectively. As previously discussed, the charging  
 499 efficiency followed very closely the output torque profile. However, a distinct behaviour was found  
 500 for the case “IVL 8, EVL 8, BP 110”. At 800 rpm this case provided similar values of charging

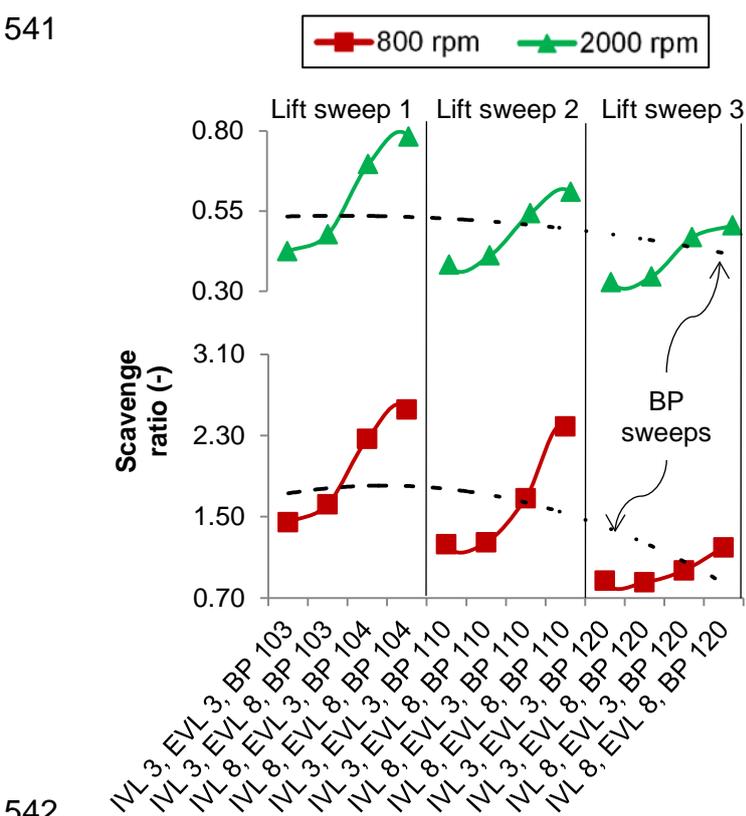

501 efficiency than the last two cases in “Lift sweep 1” where no exhaust backpressure was applied. It  
502 indicated that a moderate exhaust backpressure of 110 kPa with full valve lift (IVL 8, EVL 8, BP  
503 110) resulted in similar charging efficiency of the valve configuration for best torque (IVL 8, EVL 8,  
504 BP 104). Equivalent results were obtained at 3 mm of exhaust valve lift and no exhaust  
505 backpressure (IVL 8, EVL 3, BP 104). At 2000 rpm any exhaust throttling resulted in lower  
506 charging efficiency, although similar results of charging efficiency were again obtained with 3 mm  
507 or 8 mm of exhaust valve lift without backpressure. These results indicated that the exhaust was  
508 more efficient than the intake during the scavenging process, so the exhaust valves were  
509 oversized (or the intake valves were undersized) for the range of speeds evaluated. The poorer  
510 intake performance was a result of smaller inlet valves and the masked region around them.

511 Overall, charging efficiency was less affected by exhaust backpressure at 2000 rpm than at  
512 800 rpm as seen by the dashed lines in Figure 15. Therefore, the exhaust backpressure offered by  
513 a turbocharger at higher engine speeds would not necessarily hinder the charging process, so part  
514 of the exhaust gas energy could be recovered. Results presented by [42] for a two-stroke poppet  
515 valve diesel engine suggested the use of a large turbocharger for scavenging the burned gases at  
516 high engine speeds only. Meanwhile, the low speed charging was ensured by a crankshaft driven  
517 supercharger. This configuration guaranteed minimum exhaust backpressure at low speeds but a  
518 moderate value at higher engine speeds.

519 While charging efficiency remained similar in the last two cases of “Lift sweep 1” and in the  
520 last case of “Lift sweep 2”, lower torque was observed at any valve lift or exhaust backpressure  
521 other than the optimum case of “IVL 8, EVL 8, BP 104”. This mismatch between torque and  
522 charging efficiency was attributed to higher in-cylinder temperatures resulted from more residual  
523 gas trapped at poorer exhaust flow (either because of lower lift or backpressure). In this case the  
524 spark timing was retarded to avoid knocking combustion and hence a lower torque was obtained.  
525 In Figure 16 it is observed that a higher scavenge ratio was found for the case “IVL 8, EVL 8, BP  
526 104”. This meant that even at the same value of charging efficiency a larger portion of fresh air  
527 mass was delivered to the engine and reduced the charge temperature. The spark timing in this  
528 case was assessed and it was found that the ignition timing was advanced by 2° CA at 800 rpm

529 and 4° CA at 2000 rpm towards MBT. At a constant value of charging efficiency and by increasing  
 530 the scavenge ratio, the air trapping efficiency was expected to drop according to Equation (4). This  
 531 was the situation as seen in Figure 17, once it dropped by 11% due to the use of 8 mm of EVL.

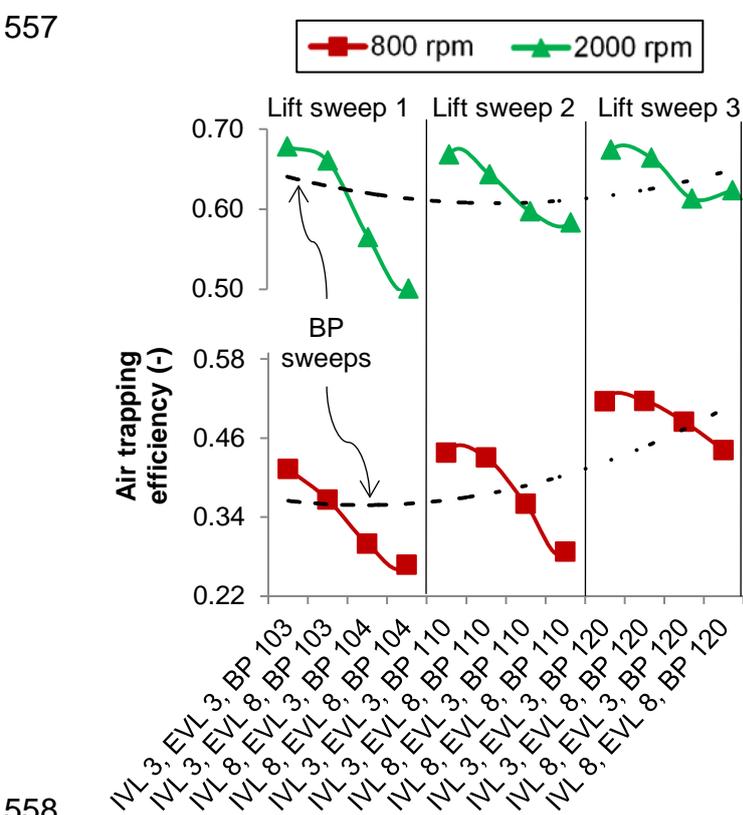

532 At both engine speeds the scavenge ratio dropped as the exhaust backpressure increased.  
 533 This was obvious considering that the lower intake-exhaust pressure ratio drove less fresh air  
 534 through the engine. The same trend was observed for the reduction in IVL and EVL as the valve  
 535 effective flow area dropped. The reduction in scavenge ratio had a positive impact on air trapping  
 536 efficiency at both speeds as seen in Figure 17. This was particularly the case when IVL was  
 537 reduced from 8 mm to 3 mm and/or exhaust backpressure was set to its maximum value of 120  
 538 kPa. At 2000 rpm, 8 mm of IVL/EVL, and an exhaust backpressure of 110 kPa, the air trapping  
 539 efficiency increased by 17% compared to the natural exhaust backpressure offered by the pipes  
 540 and silencer.

542  
 543 Figure 16 – Scavenge ratio results for the valve lift and exhaust backpressure sweeps.

544 At 8 mm of IVL the mask capacity of maintaining high values of air trapping efficiency  
 545 deteriorated. For instance, at 2000 rpm it dropped by 17% when the intake valve lift increased from  
 546 3 mm to 8 mm as shown in the plot “Lift sweep 1” in Figure 17. Air trapping efficiency dropped

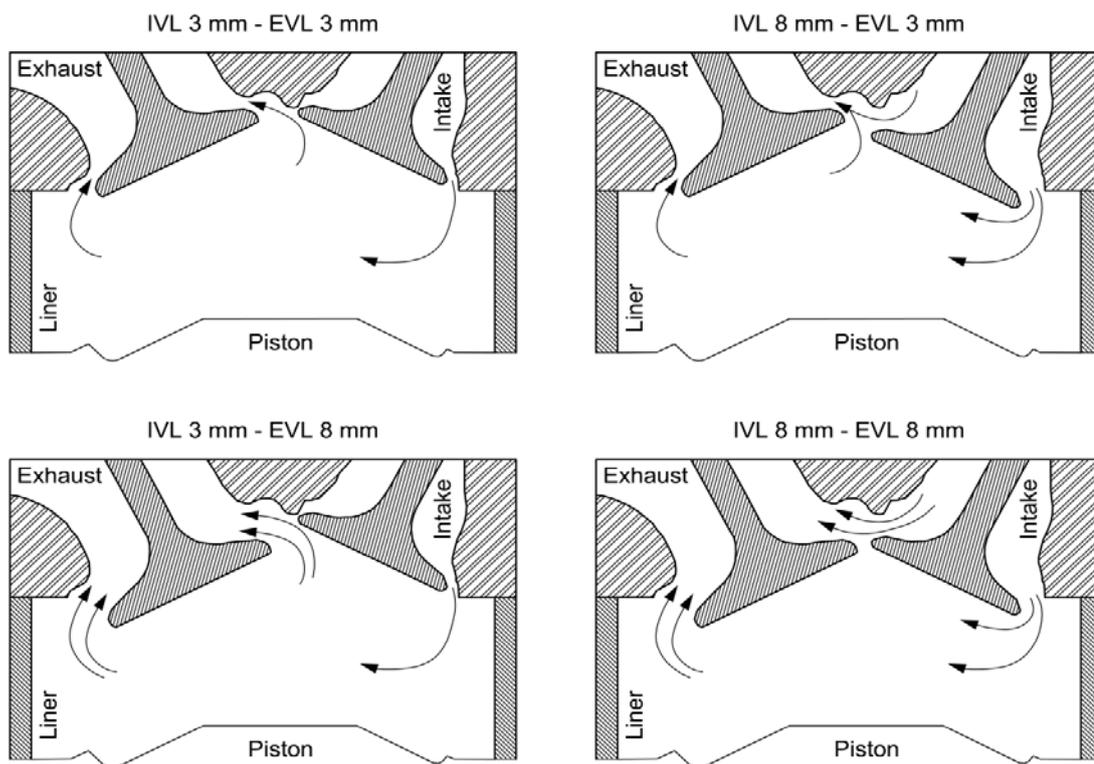

547 further 12% when EVL increased from 3 mm to 8 mm as a result of increased valve effective flow  
 548 area. There was also a peculiarity that reduced the air trapping efficiency when all valves were  
 549 operated at maximum lift as seen in the last quadrant of Figure 18. Due to the increased pent-roof  
 550 angle of the combustion chamber (126°), necessary to accommodate the four valves, fuel injector,  
 551 and spark plug, there was a short path defined between intake and exhaust valves at full lift. This  
 552 region enhanced the air short-circuiting and decreased air trapping efficiency. It could be observed  
 553 that the exhaust backpressure raised by 1 kPa as the IVL increased from 3 mm to 8 mm (lift sweep  
 554 1), which justified this effect. Meanwhile, 3 mm of IVL minimised the air short-circuiting regardless  
 555 the EVL employed. When 3 mm of lift was used for IVL and EVL (first quadrant in Figure 18), there  
 556 were fewer paths for air short-circuiting to occur.

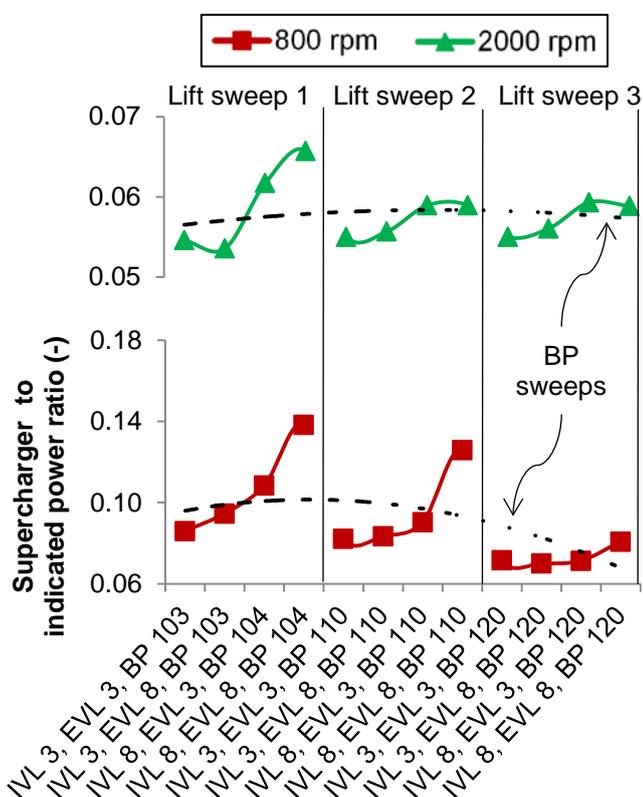

558  
 559 Figure 17 – Air trapping efficiency results for the valve lift and exhaust backpressure sweeps.

560 It is interesting to note the steep rise in supercharger power consumption (Figure 19) as the  
 561 exhaust valve lift was increased from 3 mm to 8 mm at 800 rpm. Such increase was caused by the  
 562 short air path seen in Figure 18, even though its effect was attenuated at higher exhaust  
 563 backpressures. At 2000 rpm the most perceptible difference in supercharger power consumption

564 took place as the IVL increased from 3 mm to 8 mm regardless the EVL used. This resulted from  
 565 air trapping efficiency losses as the intake valves uncovered the masked region.

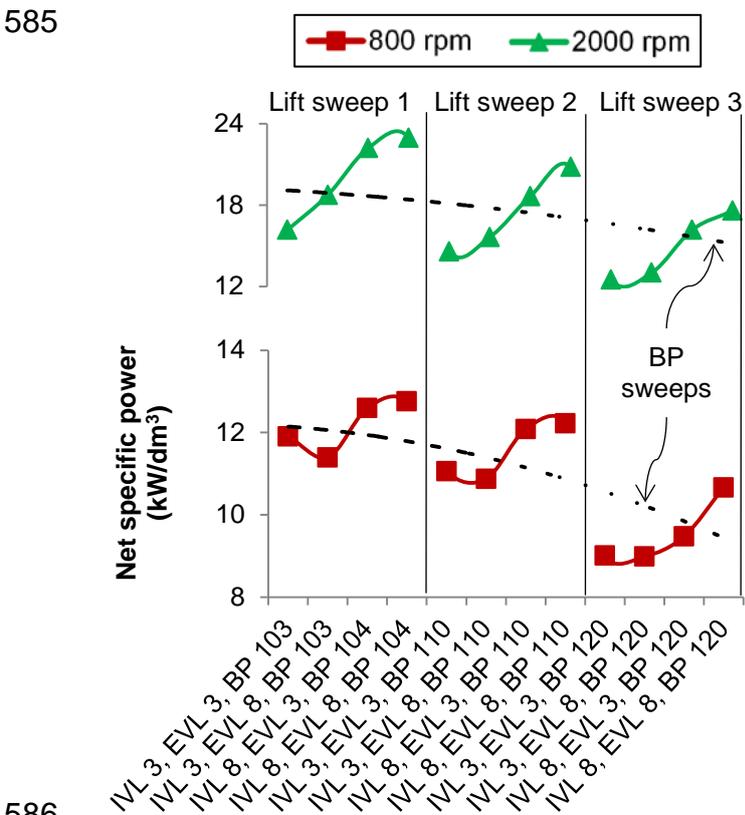

566  
 567 Figure 18 – Schematic representation of in-cylinder flow pattern at different valve lifts.

569  
 570 Figure 19 – Ratio of supercharger power requirement to engine indicated power for the valve lift  
 571 and exhaust backpressure sweeps.

572 The net indicated specific power, presented in Figure 20, was calculated by subtracting the  
 573 supercharger power consumption from the indicated power. At both engine speeds the maximum  
 574 net power was achieved with no exhaust backpressure and full valve lift (IVL 8, EVL 8, BP 104).  
 575 However, the difference in net power to the case with 3 mm of EVL (IVL 8, EVL 3, BP 104)  
 576 remained low at both engine speeds. Therefore, a reduced EVL could increase air trapping  
 577 efficiency without significantly deteriorating the output power. At 800 rpm this difference in net  
 578 power was found below 2%, while at 2000 rpm it increased to about 3%. In addition, at 800 rpm an  
 579 exhaust backpressure of 110 kPa could be applied with 8 mm of IVL/EVL without excessively  
 580 compromising the output power compared to “IVL 8, EVL 8, BP 104”. In this scenario the net  
 581 specific power reduced by about 4%, while air trapping efficiency improved by 8%. The reduction  
 582 in exhaust dilution is favourable for aftertreatment systems as the exhaust gas temperature  
 583 enhances and its oxygen content decreases. This fact impacts not only on the conversion  
 584 efficiency of catalysts but also on the energy available in case of turbocharging.

586  
 587 Figure 20 – Net indicated specific power results for the valve lift and exhaust backpressure  
 588 sweeps.

589 Data presented in Figure 20 should be interpreted with caution, once the backpressure  
590 resulted from the application of a turbocharger would provide boosted intake air. Thus, it would  
591 enhance the net specific power of the cases on the right end of Figure 20 depending on the  
592 synergy and efficiency of the boosting system (supercharger + turbocharger).

#### 593 **4. Conclusions**

594 Performance and gas exchanging of a two-stroke GDI engine with overhead poppet valves  
595 were evaluated at different valve timings, valve lifts and exhaust backpressures. Lower engine  
596 speeds benefited from shorter intake/exhaust valve opening durations. Meanwhile, at higher  
597 speeds the time available for gas exchange shortened and longer valve opening durations were  
598 required. Very long intake/exhaust opening durations, although, deteriorated the effective  
599 compression/expansion ratios and air trapping efficiency. Thus, the indicated power reduced and  
600 the supercharger power consumption increased at higher air short-circuiting rates. Similarly,  
601 excessively short valve opening durations resulted in poor charging efficiency and large amounts  
602 of residual gas trapped, requiring more retarded spark timings to avoid knocking combustion.  
603 Despite the improvements in EER and ECR, this condition resulted in deteriorated torque  
604 particularly at 2000 rpm. In all tests it was found a strong correlation between torque and charging  
605 efficiency, while air trapping efficiency was associated to exhaust valve opening duration.

606 With IVO at 130°, IVC at 240°, EVO at 120° and EVC at 230° CA ATDC, the engine  
607 performance was found satisfactory at both speeds tested. The 10° CA between EVO and IVO  
608 enabled an effective exhaust blowdown phase to take place without intake backflow. The 10° CA  
609 between EVC and IVC improved the charge purity at the onset of compression by means of a  
610 “supercharging effect”. This valve configuration was further evaluated regarding different intake  
611 and exhaust valve lifts and the effect of exhaust backpressure.

612 Any combination of intake and exhaust valve lifts, apart from 8 mm, resulted in torque  
613 deterioration at both speeds. At low intake valve lifts there were modest gains by opening the  
614 exhaust valves beyond the same values of lift. In addition, air trapping efficiency and supercharger  
615 power consumption were greatly improved by limited valve openings. Overall, the higher the

616 exhaust backpressure, the lower was the output torque at both engine speeds. Nevertheless, the  
617 charging efficiency was less affected by the exhaust backpressure at higher engine speeds. At 800  
618 rpm the air trapping efficiency could be improved by either lower exhaust valve lift or modest  
619 exhaust backpressure without compromising net power.
