The Origins of Religious Disbelief: A Dual Inheritance Approach

Will M. Gervais¹, Maxine B. Najle², and Nava Caluori³

Abstract

Widespread religious disbelief represents a key testing ground for theories of religion. We evaluated the predictions of three prominent theoretical approaches—secularization, cognitive byproduct, and dual inheritance—in a nationally representative (United States, \(N = 1,417\)) data set with preregistered analyses and found considerable support for the dual inheritance perspective. Of key predictors of religious disbelief, witnessing fewer credible cultural cues of religious commitment was the most potent, \(\beta = .28\), followed distantly by reflective cognitive style, \(\beta = .13\), and less advanced mentalizing, \(\beta = .05\). Low cultural exposure predicted about 90% higher odds of atheism than did peak cognitive reflection, and cognitive reflection only predicted disbelief among those relatively low in cultural exposure to religion. This highlights the utility of considering both evolved intuitions and transmitted culture and emphasizes the dual roles of content- and context-biased social learning in the cultural transmission of disbelief (preprint https://psyarxiv.com/e29rt/).

Keywords

atheism, religion, culture, evolution, dual inheritance theory

Evolutionary approaches to religion have proliferated in recent years, and different theories make starkly different predictions about the existence, nature, and origins of religious disbelief. Atheists—merely people who do not believe in the existence of a God or gods—constitute a large and perhaps growing proportion of earth’s human population. A prominent estimate from about a decade ago (Zuckerman, 2007) posits the existence of 500–700 million atheists globally. This estimate is in all likelihood a drastic underestimate (Gervais & Najle, 2018). People routinely overreport their religious practices (Hadaway et al., 1993), and indirect measurement of atheism in the United States reveals a potentially large gulf between some indirect (~26%) and direct (~3%) estimates of atheist prevalence (Gervais & Najle, 2018). Combining direct estimates and inferences drawn from the few available indirect estimates, we suspect that upward of 2 billion people on earth may in fact be atheists. Many evolutionary theories of religion posit a universal or near-universal implicit theism (Barrett, 2004, 2010; Bering, 2010; Boyer, 2008) and may thus be fundamentally incompatible with global atheism that is simultaneously prevalent and deliberately concealed. Here, we test predictions on atheism from three prominent theoretical frameworks, as outlined in Table 1: secularization, cognitive byproduct, and an emerging dual inheritance model of religion (Norenzayan & Gervais, 2013; Norenzayan et al., 2016). This project situates the study of religious disbelief firmly within established theoretical frameworks for studying the evolution of human behavior and contributes to broader discussions of the role of transmitted versus evoked culture in core aspects of human nature (Laland & Brown, 2011).

Prominent Theoretical Approaches

Three of the most prominent current approaches to religion and disbelief are secularization theories, the cognitive byproduct approach made popular by evolutionary psychology and the cognitive science of religion, and a dual inheritance approach.

Secularization. Secularization theories emerging from sociology of religion (Inglehart & Norris, 2004; Marx, 1843; Schnabel, 2020) and social psychology (Inzlicht et al., 2011; Kay et al., 2008) posit that religions serve some sort of societal or intrapsychic function, be it for bringing groups together or assuaging existential concerns. As strong secular institutions emerge in some places (Inglehart & Norris, 2004) or in situations in which people feel secure and secular institutions can quench a thirst for control and order (Kay et al., 2008), religious motivations...
The challenge of actually believing in one (Gervais & Henrich, 2010). To tackle mentally representing or remembering a supernatural agent to (Barrett, 2004; Boyer, 2008). However, it is a far step from mentally representing or remembering a supernatural agent to actually believing in one (Gervais & Henrich, 2010). To tackle the challenge of belief in (rather than just mental representation of) supernatural agents, work from cultural evolution and gene–culture coevolution has emphasized that religious belief emerges from the interaction of evolved cognitive architecture and cultural learning.

In this view, people are biased to learn some concepts rather than others due to either their contents (some ideas are memorable and evocative) or from the learning context. Several context-dependent learning strategies may be especially important in religious belief and disbelief. Conformist transmission (learning common beliefs; Henrich & Boyd, 1998), prestige-and success-biased learning (learning from winners; Henrich & Gil-White, 2001), and behavioral cues diagnostic of underlying beliefs—termed credibility-enhancing displays (CREDS; Henrich, 2009)—combine to powerfully influence what people come to believe or disbelieve. This dual inheritance approach does predict that religious belief will be widespread but also predicts that atheism might naturally result in cultural contexts devoid of consistent behavioral cues that a naive learner ought to believe in any given god (Gervais & Henrich, 2010; Gervais & Najle, 2015; Lanman, 2012; Lanman & Buhrmester, 2017). In a dual inheritance framework, the individual differences in reflection or mentalizing highlighted by cognitive byproductists may predict atheism, but cultural cues are probably much more important.

These three broad approaches—secularization, cognitive byproduct, and dual inheritance—make similar predictions about religious belief: namely that it ought to be quite widespread. They make sharply divergent predictions, however, about the nature of disbelief. It is sensible, therefore, to consider the various potential predictors of religious disbelief as a way to contrast the various theories.

### Four Pathways to Atheism

Distinct research trajectories have considered the preconditions for sustained belief in any given god. To currently believe in a god, one (1) must be able to mentally represent gods (Gervais, 2013; Norenzayan et al., 2012; Purzycki & McNamara, 2016; Willard & Norenzayan, 2013), (2) must be dispositionally or situationally motivated to believe in some gods (Kay et al., 2008), (3) must receive credible cultural cues that some gods are real (Gervais & Henrich, 2010; Gervais & Najle, 2015; Lanman & Buhrmester, 2017), and (4) must maintain this intuitive belief over time. Tweaks to any of these four components may instead yield disbelief in gods. Separate lines of research partially support this supposition. First, mindblind atheism

Note. + Symbols indicate the predicted strength of each pathway to atheism by theory. Mindblind = relatively lower in advanced mentalizing; apatheist = relatively more existentially secure; inCREDulous = exposed to relatively fewer religious credibility-enhancing displays; analytic = scoring relatively higher on cognitive reflection.
describes the pattern whereby individual differences in advanced mentalizing abilities predict religious disbelief (Norenzayan et al., 2012; Willard & Norenzayan, 2013) in at least some samples (Maj et al., 2017). Second, apatheism describes the pattern whereby, although people are highly religiously motivated when life is insecure, unstable, and unpredictable, existential security instead predicts reduced religiosity (Inglehart & Norris, 2004; Kay et al., 2008). Third, inCREDulous atheism describes the pattern whereby a lack of CREDs (Henrich, 2009) that one ought to believe in any gods is a good global predictor of atheism (Gervais & Najle, 2015; Lanman, 2012). Finally, analytic atheism describes the pattern whereby people who reflectively override their intuitions tend to be less religious than those who “go with their guts” (Pennycook et al., 2016; Shenhav et al., 2012), although the magnitude and consistency of this relation are debatable (Gervais et al., 2018).

Predictions
Prominent theoretical approaches make subtly diverging predictions about which pathways to atheism (mindblind, apatheism, inCREDulous, or analytic) are most important (see Table 1). First, secularization models (Inglehart & Norris, 2004; Kay et al., 2008; Vail et al., 2012) posit that increases in existential security (wealth, health, education, etc.) reduce religious motivation. Thus, secularization approaches would predict that measures of existential security and secular institutions (general feelings of safety, faith in police, etc.) ought to be primary predictors of atheism. Apatheism is the most important pathway to disbelief per secularization theories.

Second, cognitive science of religion and evolutionary psychology often view religion as a cognitive byproduct of other mental adaptations (Barrett, 2004; Boyer, 2008) such as mind perception (Gervais, 2013) or predator detection. In this view, challenges in the core cognitive faculties underlying such adaptations (e.g., advanced mentalizing) would predict disbelief, but the primary route to disbelief is people overriding their religious intuitions via effortful cognitive reflection. Analytic atheism is the most important pathway to disbelief per cognitive byproduct theorists.

Finally, dual inheritance models highlight the cultural learning processes (Kline, 2015; Rendell et al., 2011) underpinning religious beliefs (Evans, 2001; Lane et al., 2012; Richert et al., 2017; Willard et al., 2016) and disbelief and largely predict that context-biased social learning—especially CREDs (Henrich, 2009)—would be strongly associated with degrees of religious belief (Gervais & Najle, 2015). Our dual inheritance approach predicts that CREDs would be most important, followed by other factors such as cognitive reflection, mentalizing, and perhaps existential security. InCREDulous atheism is central to dual inheritance approaches to religious disbelief.

We preregistered a set of analyses to simultaneously evaluate the predictions of secularism, cognitive byproduct, and dual inheritance models, https://osf.io/kfasv, in a probability sample of U.S. American adults. Specifically, we posed three broad questions:

What are the relative predictive contributions of each pathway to atheism when considered simultaneously?
How do the four pathways interact with each other in predicting disbelief?
Does early work on each individual pathway successfully replicate in a nationally representative sample?

To approach these questions, we contracted Growth from Knowledge (GfK) to collect a nationally representative sample of U.S. American adults (N = 1,417). Primarily, we were interested in predicting degrees of religious belief and disbelief with measures of (1) advanced mentalizing, (2) existential security, (3) exposure to religious CREDs, and (4) cognitive reflection. For robustness, we tested models using both continuous and dichotomous measures of religious disbelief. We also included a number of demographic and personality covariates to adjust for theory-adjacent but nonetheless documented correlates of religiosity. Full materials, data, and code are available at https://github.com/wgervais/disbelief-origins.

Method
Sample
We contracted GfK, which specializes in nationally representative sampling, to gather a probability sample of U.S. American adults. This national probability sample included 1,685 individuals that were broadly representative of the American population in terms of gender (50.14% female, 49.86% male, 0.35% listing another gender), age (M = 50.58, SD = 16.83), race/ethnicity, education, census region, household income, homeownership status, and residence within a metropolitan area. We excluded 268 participants who failed an attention check or who did not complete all measures, leaving a total of 1,417 respondents (see Table 2). Inferences do not appreciably change under alternate exclusion criteria.

Measures
Religious belief: We tested models with two separate religious disbelief measures. First, we relied on a popular continuous measure of religious belief, the Supernatural Beliefs Scale (Jong et al., 2013), as our main dependent measure of religious belief. This scale was reliable, α = .95, M = 4.91, SD = 1.63. As a robustness check, we also included a binary item in which participants simply indicated whether or not they believe in God.

We also included various other measures of religiosity, which were used to gain a more fine-grained understanding of the demographics of our sample and are summarized in Table 2. For example, we asked participants how often they attended services outside of weddings and funerals and how often they pray. We also asked participants to indicate the religion with which they identify, and they were allowed to select multiple applicable categories (e.g., “atheist” and “agnostic”). We included these variables primarily for descriptive purposes.
Pathways to religious disbelief. We measured participants’ mentalizing abilities, feelings of existential security, exposure to credible cues of religiosity (CREDs), and reflective versus intuitive cognitive style.

We measured advanced mentalizing abilities, which correspond to mindblind atheism, using the Perspective Taking subscale of the Interpersonal Reactivity Index (Davis, 1980). This scale reached an acceptable level of reliability, $\alpha = .77$, $M = 4.79$, $SD = 0.78$.

We measured feelings of existential security, which corresponds to apatheism, with a number of items assessing concerns that are salient to participants and participant faith in institutions like the government, health care, and social security to provide aid in the face of need (Willard & Cingl, 2017). Items measuring faith in institutions were reverse-scored, and all items were averaged together to form a composite index of existential insecurity ($\alpha = .77$, $M = 2.2$, $SD = 0.39$).

We measured cognitive reflection, which corresponds to analytic atheism, using nine items from the cognitive reflection test (Frederick, 2005; Primi et al., 2016; Toplak et al., 2014). Our full index of cognitive reflection is composed of the sum of the nine questions that each participant answered correctly, with a higher score thus indicating a more reflective and analytic cognitive style. The average score was 3.18, with an $SD$ of 2.66.

We measured exposure to CREDs, which corresponds to inCREDulous atheism, with the CREDs Scale (Lanman & Buhrmester, 2017). This scale assesses the extent to which caregivers demonstrated religious behaviors during the respondent’s childhood, such as going to religious services, acting as good religious role models, and making personal sacrifices to religion. This scale was highly reliable, $\alpha = .93$, $M = 2.42$, $SD = 0.84$.

Personality measures. We used the Mini-IPIP6 (Milojev et al., 2013) to measure the personality factors of extroversion ($\alpha = .79$, $M = 3.69$, $SD = 1.12$), agreeableness ($\alpha = .75$, $M = 4.96$, $SD = 0.92$), conscientiousness ($\alpha = .68$, $M = 4.97$, $SD = 0.97$), neuroticism ($\alpha = .75$, $M = 3.52$, $SD = 1.08$), openness to experience ($\alpha = .73$, $M = 4.69$, $SD = 1.01$), and honesty–humility ($\alpha = .76$, $M = 4.8$, $SD = 1.13$).

General demographics. Finally, we included a demographics questionnaire to adjust for known religion-predictive participant characteristics. We assessed education level by asking participants what their highest level of education was, from no formal education to professional or doctorate degree. We used single face–valid items to assess both social (1 = very liberal to 7 = very conservative; $M = 4.07$, $SD = 1.77$) and economic (1 = very liberal to 7 = very conservative; $M = 4.36$, $SD = 1.54$) political ideology.

Correlations. Correlations among all analyzed variables appear in Figure 1 and Table 3.

Results
Analytic Strategy
We used Bayesian estimation throughout this study. Bayesian estimation allows us to evaluate the credibility of different parameter estimates, given data and statistical models (Etz & Vandekerckhove, 2018; Kruschke, 2010, 2013; McElreath, 2016; Wagenmakers et al., 2016). Most analyses report a point estimate reflecting the most credible parameter estimate and

Note. $\beta =$ standardized coefficient; HPDI = 97% highest posterior density interval; $p(\beta > 0) =$ posterior probability of $\beta > 0$; CREDs = credibility-enhancing displays.

the highest posterior density interval (HPDI), the region in which 97% of most credible estimates lie. We chose 97% coverage because it is no more arbitrary than any other cutoff but provides a very conservative range of plausible values. We also report a variety of posterior probabilities, which state the probability of something ($\beta > 0$, etc.) being true, given data and model. Heuristically, the posterior probabilities have the properties people misintuit frequentist $p$ values as having (e.g., the probability of some hypothesis being true; Oakes, 1986), and the HPDIs have the properties people misintuit frequentist confidence intervals as having (e.g., the probability that a parameter lies in that range; Hoekstra et al., 2014). We used gently regularizing priors throughout, primarily deployed to buffer against model overfitting. Inferences are highly robust to nondiludic alternative priors. Full materials, data, and code are available at https://github.com/wgervais/disbelief-origins.

Simultaneous Contributions

Our most important analyses considered the simultaneous contributions of all four pathways operating in concert. As preregistered, we conducted analyses in which the four core factors predict individual differences in belief and disbelief, both in the presence and absence of additional covariates. Multicollinearity among key predictors was not problematic, correlations ranged from $r = -.12$ to .22. In our full model predicting a continuous multiitem measure of religious disbelief (see Measures section, for details), witnessing fewer credible displays of faith proved to be by far the most powerful predictor of religious disbelief (see Table 4 and Figure 2). CREDs of faith predict belief, and their absence predicts atheism, $\beta = .28$, [0.23, 0.34], $p(\beta > 0 | \text{data}) = 1.5$. Cognitive reflection remained a consistent predictor of religious disbelief, $\beta = .13$, [0.07, 0.19], $p(\beta > 0 | \text{data}) = 1$, but following earlier cross-cultural work (Gervais et al., 2018), its predictive power was relatively meager. Lower scores on a measure of advanced mentalizing abilities were reliably but weakly associated with disbelief, $\beta = .05$, [-0.01, 0.11], $p(\beta > 0 | \text{data}) = 0.96$, and existential security predicted essentially nothing. Relatively, fewer religious CREDs were the strongest predictor of atheism when all four potential pathways are considered simultaneously.

Atheism: Binary measure. We also measured religious disbelief with a simple binary (no, yes) belief in God item. As a robustness check, we reran our full model analysis as a logistic model predicting atheism rates on the binary measure. Unsurprisingly, results closely matched the continuous full model. Aside from demographic covariates, only few religious CREDs, $\beta = .83$, [0.61, 1.05], $p(\beta > 0 | \text{data}) = 1$, and more cognitive reflection, $\beta = .38$, [0.17, 0.59] = $p(\beta > 0 | \text{data}) = 1$, predicted atheism. However, fewer religious CREDs again emerged as a stronger predictor of atheism than did cognitive reflection. To illustrate, we considered the posterior produced by our model, marginalized at various levels of our predictors. Specifically, we compared the hypothetical probability of atheism for model-predicted individuals who are either perfectly inCREDulous (scoring at the floor for religious CREDs) but typical on all other variables or else perfectly analytical (scoring at ceiling on cognitive reflection) but otherwise typical. The predicted odds of atheism are about 90% higher for a purely inCREDulous individual, $p(\text{atheism} | \text{inCREDulous}) = .31$, [0.24, 0.39], than for a purely analytic individual, $p(\text{atheism} | \text{analytic}) = .20$, [0.13, 0.28], odds ratio = 1.87, [0.93, 3.03], $p(\text{inCREDulous} > \text{analytic} | \text{data}) = 0.99$. This relative difference in predictive strength for CREDs and cognitive reflection, replicated across continuous and binary measures of disbelief, is most consistent with a dual inheritance approach.

Hypothesized Interactions

Next, we probed for preregistered interactions finding an interaction between cultural learning and reflective cognitive style, $\beta = -.08$, [-0.12, -0.03], $p(\beta > 0 | \text{data}) = 1$. We considered the association between disbelief and reflective cognitive style among those comparatively high and low on religious CREDs (Figure 3), finding that reflective cognitive style primarily predicts religious disbelief among those who were also comparatively low in cultural exposure to credible religious cues of faith. Indeed, cognitive reflection moderately predicted religious disbelief among those witnessing the fewest religious CREDs, $\beta = .26$, [0.15, 0.35], $p(\beta > 0 | \text{data}) = 0$, but not at all among those highest in religious CREDs, $\beta = -.01$, [-0.13, 0.10], $p(\beta > 0 | \text{data}) = 0.6$. These patterns highlight the interactive predictive roles of cultural context and evolved intuitions on religious cognition. This interaction is consistent with a dual inheritance perspective but not obviously predicted by other prominent theoretical approaches.
Overall, this study is one of the most comprehensive available analyses of the cognitive, cultural, and motivational factors that predict individual differences in religious belief and disbelief (see also Willard & Cingl, 2017). Consistent patterns emerged, suggesting that lack of exposure to CREDs of religious faith is a key predictor of atheism. Once this context-biased cultural learning mechanism is accounted for, reflective cognitive style predicts some people being slightly more prone to religious disbelief than their cultural upbringing might otherwise suggest.

That said, this relationship was relatively modest. Advanced mentalizing was a robust but weak predictor of religious belief, and existential security did not meaningfully predict disbelief. This overall pattern of results closely matched predictions of a dual inheritance approach but is difficult to reconcile with other prominent theoretical approaches (see Table 1 and Figure 2). These results speak directly to competing for theoretical perspectives on the origins of religious disbelief culled from sociology, social psychology, evolutionary psychology, cognitive science of religion, cultural evolution, and gene–culture coevolution.

**Alternatives and Limitations**

Of the four primary atheism predictors that we used to test prominent theories, religious CREDs emerged as a clear empirical winner. In some ways, however, our tests may have been methodologically stacked in this variable’s favor. Like the self-reports of religious disbelief, this measure includes self-report items about religious upbringing. Thus, there is shared method variance associated with this predictor that is less evident for others. Also, although the CREDs–atheism relationship is consistent with a cultural transmission framework, heritability of religiosity may also contribute to atheists coming from families who aren’t visibly religious. The measure we used is unable to resolve this. Further, our various key predictors varied in both reliability and demonstrated validity. We chose these measures simply because they have been used in previous research; that said, previous use does not necessarily imply that the measures were sufficient.

As with measurement quality, sample diversity is a recurrent concern in psychological research (Henrich et al., 2010; Rad et al., 2018; Saab et al., 2020). Most psychology research nowadays emerges from convenience samples of undergraduates and Mechanical Turk workers. These samples are fine for some purposes, quite limited for others (Gaither, 2019), and are known to depart from representativeness (Callegaro et al., 2014; MacInnis et al., 2018). While our nationally representative sampling allows us to generalize beyond samples, we can access for free (in lab) or cheap (MTurk), even a large nationally representative sample barely scratches the surface of human diversity (Henrich et al., 2010; Rad et al., 2018; Saab et al., 2020). As such, we encourage similar analyses across different cultures (Willard & Cingl, 2017). Diversifying the samples that make up the empirical portfolio of evolutionary approaches to religion is especially necessary because cultural cues themselves emerged as the strongest predictor of disbelief in this and related work (Gervais & Najle, 2015; Gervais et al., 2018; Maij et al., 2017; Willard & Cingl, 2017). Without diverse samples, including and especially extending well beyond nationally representative samples in the United States, researchers can only aspire to ever more precisely answer a mere outlier of an outlier of our most important scientific questions about human nature.

We measured and tested predictors of religious belief and disbelief. This outcome measure is quite narrow in scope, in
terms of the broader construct of religiosity. Further, our Supernatural Belief Scale—while it has been used across cultures—is fairly Judeo-Christian-centric. We suspect that a broader consideration of religiosity in diverse societies may yield different patterns. The Western, Educated, Industrialized, Rich, Democratic (WEIRD) people problem isn’t just a sampling issue; it also reflects an overreliance on the theories, constructs, and instruments developed by WEIRD researchers to test their weird hunches.

Although it is not featured in any of the core theoretical perspectives we evaluated, social liberalism was consistently the strongest covariate of religious disbelief. The intersection of religious and political ideology is an interesting topic in its own right and merits further consideration. Interestingly, disbelief if anything was associated with fiscal conservatism in this sample. This suggests that simple “believers are conservative” tropes are oversimplifications. Ideology and religiosity are multifaceted and dissociable, but certainly of interest given rampant political polarization in the United States and elsewhere. That said, religion–ideology associations, whatever they may be, are largely orthogonal to existing cultural and evolutionary theories of religious belief and disbelief.

**Theoretical Implications**

We simultaneously evaluated predictions about the origins of disbelief from three prominent theoretical perspectives: secularization, cognitive byproduct, and dual inheritance. Comparing the predictions in Table 1 with the results of Figure 2, results were most consistent with the dual inheritance perspective, the only theoretical perspective that predicted prominent roles for both inCREDulous atheism and analytic atheism. Given the primacy of cultural learning in our data, any model that does not rely heavily on context-biased cultural learning is likely a poor fit for explaining the origins of religious disbelief. By extension, such theoretical models are necessarily incomplete or faulty evolutionary accounts of religion. Simply growing up in a home with relatively fewer credible displays of faith predicted disbelief, contra prior assertions from the cognitive science of religion that disbelief results from “special cultural conditions” and “a good degree of cultural scaffolding” (Barrett, 2010).

Analytic atheism is probably the most discussed avenue to disbelief in the literature (Pennycook et al., 2016; Shenhav et al., 2012) and broader culture (Dawkins, 2006). Although in this sample, there was consistent evidence of analytic atheism, the overall trend was modest, the trend itself varied considerably across exposure to CREDs, and sufficient religious CREDs buffered believers against the putatively corrosive influence of reflective cognition on faith. Despite claims that atheism generally requires cognitive effort or reflection (Barrett, 2010; Boyer, 2008), cognitive reflection was only modestly related to atheism in these data. These results, taken alongside other evidence accumulating from similar studies (Farias et al., 2017; Gervais et al., 2018; Willard & Cingl, 2017), may suggest that early claims surrounding the primacy of effortful cognitive reflection as a necessary predictor of atheism may have been overenthusiastic. Analytic thinking predicts atheism in some contexts but is far from primary.

It is initially puzzling that existential security proved largely impotent in our analyses, as it appears to be an important factor in explaining cross-cultural differences in religiosity (Barber, 2013; Inglehart & Norris, 2004; Solt et al., 2011). It is possible that our analyses were at the wrong level of analysis to capture the influence of existential security, which may act as a precursor to other cultural forces. There may actually be a two-stage generational process whereby existential security demotivates religious behavior in one generation, leading the subsequent generation to atheism as they do not witness CREDS of faith. This longitudinal societal prediction merits future investigation.

Finally, this work has implications beyond religion. Presumably, many beliefs arise from an interaction between core cognitive faculties, motivation, cultural exposure, and cognitive style. The general dual inheritance framework adopted here may prove fruitful for other sorts of beliefs elsewhere. Indeed, a thorough exploration of the degree to which different beliefs are predicted by cultural exposure relative to other cognitive factors may be useful for exploring content- versus context-biased cultural learning and the contributions of transmitted and evoked culture. As this is a prominent point of contention between different schools of human evolutionary thought (Laland & Brown, 2011), such as evolutionary psychology and cultural evolution, further targeted investigation may be productive.

**Coda**

The importance of transmitted culture and context-biased cultural learning as a predictor of belief and disbelief cannot be overstated. Combined, this work suggests that if you are guessing whether or not individuals are believers or atheists, you are better-off knowing how their parents behaved—Did they tithe? Pray regularly? Attend synagogue?—than how they themselves process information. Further, our interaction analyses suggest that sufficiently strong cultural exposure yields sustained religious commitment even in the face of the putatively corrosive influence of cognitive reflection. Theoretically, these results fit well within a dual inheritance approach, as evolved cognitive capacities for cultural learning prove to be the most potent predictor of individual differences in the cross-culturally canalized expression of religious belief. Atheists are becoming increasingly common in the world, not because human psychology is fundamentally changing but rather because evolved cognition remains fairly stable in the face of a rapidly changing cultural context that is itself the product of a coevolutionary process. Faith emerges in some cultural contexts, and atheism is the natural result in others.

**Authors’ Note**

This project was approved by the Office of Research Integrity at the University of Kentucky. https://osf.io/kfasv.
Acknowledgments
Sarah Schiavone helped with survey implementation and early data processing but declined authorship; we nonetheless acknowledge and thank her for the work on this article.

Author Contributions
W.M.G. designed the study, with survey revision and implementation from M.B.N. M.B.N. contributed feedback and piloting throughout the life of this project. W.M.G. performed the primary analyses, and N.C. performed descriptive analyses. W.M.G. wrote the article with N.C. All authors approved the final article.

Declaration of Conflicting Interests
The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Funding
The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: This research was supported by a grant to W.M.G. from the John Templeton Foundation (48275). N.S. was supported by a National Science Foundation Graduate Research Fellowship. The content is solely the responsibility of the authors and does not necessarily represent the official views of its funders. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the article.

Supplemental Material
The supplemental material is available in the online version of the article.

Notes
1. Anecdotally, many-to-most graduate students in cognitive science of religion have tried these studies to no avail.
2. Analyses treating each core pathway in isolation rather than in a single combined model are presented in the Online Supplement.
3. Note: Our precise sample demographics may look a bit different from census estimates on, for example, ethnicity or education. Growth from Knowledge provided proper probability sampling for representativeness, but our precise measures were not identical to those used by the census. Apparent discrepancies may be due to differing demographic measures and categories, rather than probability sampling errors.
4. Values in brackets are 97% highest posterior density interval.
5. $p(\beta > 0 \mid \text{data}) = 1$ indicates a posterior probability exceeding .99.
6. We preregistered a possible quadratic relationship between mentalizing and disbelief. For theoretical and statistical reasons, we depart from preregistration and don’t analyze the quadratic here. See Online Supplement for further discussion.
7. Preregistered analyses probing for interactions with mentalizing yielded nothing of particular note and are summarized in the Online Supplement.
