Untangling the complex food webs of tropical rainforest streams

Journal:	Journal of Animal Ecology
Manuscript ID	Draft
Manuscript Type:	Research Article
Key-words:	Food Webs, Metabolic Theory, Macroinvertebrates, Stable Isotopes, Stability

The meta food web of a tropical stream watershed. The width of links in the food web depicts the amount of energy fluxing from resources to consumers in a steady-state system. This system is bioenergetically stable considering a Lotka-Volterra system of equations. Simulations of individual species removal do not destabilise the food web.

1 UNTANGLING THE COMPLEX FOOD WEBS OF TROPICAL RAINFOREST STREAMS

2 ABSTRACT

Food webs depict the tangled web of trophic interactions associated with the
 functioning of an ecosystem. Understanding the mechanisms providing stability
 to these food webs is therefore vital for conservation efforts and management
 of natural systems.

7 2. Here, we first characterised a tropical stream meta food web and five individual 8 food webs using a Bayesian Hierarchical approach unifying three sources of 9 information (gut content analysis, literature compilation, stable isotope data). 10 With data on population-level biomass and individually measured body mass, 11 we applied a bioenergetic model and assessed food web stability using a Lotka-Volterra system of equations. We then assessed the resilience of the system to 12 13 individual species extinctions using simulations and investigated the network 14 patterns associated with systems with higher stability.

15 3. The model resulted in a stable meta food web with 307 links among the 61 16 components. At the regional scale, 70% of total energy flow occurred through a 17 set of ten taxa with large variation in body masses. The remaining 30% of total 18 energy flow relied on 48 different taxa, supporting a significant dependency on 19 a diverse community. The meta food web was stable against individual species 20 extinctions, with a higher resilience in food webs harbouring omnivorous fish 21 species able to connect multiple food web compartments via weak, non-22 specialized interactions. Moreover, these fish species contributed largely to the 23 spatial variation among individual food webs, suggesting that these species

24		could operate as mobile predators connecting different streams and stabilising
25		variability at the regional scale.
26	4.	Our results outline two key mechanisms of food web stability operating in
27		tropical streams: (i) the diversity of species and body masses buffering against
28		random and size-dependent disturbances (ii) high regional diversity and weak
29		omnivorous interactions of predators buffering against local stochastic
30		variation in species composition. These mechanisms rely on high local and
31		regional biodiversity in tropical streams, which is known to be strongly affected
32		by human impacts. Therefore, an urgent challenge is to understand how the
33		ongoing systematic loss of diversity jeopardises the stability of stream food
34		webs in human-impacted landscapes.

38 39	RESUN	ЛО
40	1.	As teias alimentares representam um emaranhado de interações tróficas
41		associadas ao funcionamento de um ecossistema. Compreender os
42		mecanismos que proporcionam estabilidade a estas teias alimentares é,
43		portanto, vital para os esforços de conservação e gestão dos sistemas naturais.
44	2.	Aqui, primeiro caracterizamos uma meta teia alimentar de riachos tropicais e
45		cinco teias alimentares individuais usando uma abordagem hierárquica
46		Bayesiana unificando três fontes de informação (análise de conteúdo

47	estomacal, compilação de literatura, dados de isótopos estáveis). Com dados
48	sobre biomassa em nível populacional e massa corporal medida
49	individualmente, aplicamos um modelo bioenergético e avaliamos a
50	estabilidade da cadeia alimentar usando um sistema de equações Lotka-
51	Volterra. Em seguida, avaliamos a resiliência do sistema às extinções de
52	espécies individuais usando simulações e investigamos os padrões de rede
53	associados a sistemas com maior estabilidade.

54 3. O modelo resultou em uma meta teia alimentar estável com 307 ligações entre 55 os 61 componentes. Na escala regional, 70% do fluxo total de energia ocorreu 56 através de um conjunto de dez taxa com grande variação nas massas corporais. 57 Os restantes 30% do fluxo total de energia dependiam de 47 taxa diferentes, 58 apoiando uma dependência significativa de uma comunidade diversificada. A 59 meta teia alimentar foi estável contra extinções de espécies individuais, com 60 uma maior resiliência em teias alimentares que abrigam espécies de peixes 61 onívoros capazes de conectar múltiplos compartimentos da teia alimentar 62 através de interações fracas e não especializadas. Além disso, estas espécies de 63 peixes contribuíram amplamente para a variação espacial entre as cadeias alimentares individuais, sugerindo que estas espécies poderiam operar como 64 65 predadores móveis conectando diferentes riachos e estabilizando a 66 variabilidade à escala regional.

A. Nossos resultados descrevem dois mecanismos principais de estabilidade da
cadeia alimentar operando em riachos tropicais: (i) a diversidade de espécies e
massas corporais que protegem contra distúrbios aleatórios e dependentes do

70	tamanho (ii) alta diversidade regional e fracas interações onívoras de
71	predadores que protegem contra a variação estocástica local na composição de
72	espécies. Estes mecanismos dependem de uma elevada biodiversidade local e
73	regional em riachos tropicais, que são conhecidos por serem fortemente
74	afetados pelos impactos humanos. Portanto, um desafio urgente é
75	compreender como a contínua perda sistemática de diversidade põe em risco a
76	estabilidade das teias alimentares em paisagens impactadas pelo homem.

79	
80	INTRODUCTION
81	Food webs depict the tangled web of trophic interactions associated with the
82	transfer of energy within an ecosystem. These ecological networks offer mechanistic
83	insights into energy flow, nutrient cycling, and population dynamics, highlighting
84	critical links that influence the stability and resilience of natural ecosystems.
85	Consequently, food webs provide a vital tool for conservation efforts and ecosystem
86	management, allowing better-informed decisions about how to protect and preserve
87	the functioning of natural systems (Giakoumi et al., 2015). Therefore, understanding
88	the mechanisms that govern food web stability with precision and detail is pivotal to
89	improve our understanding of ecosystem functioning in the face of the current
90	environmental crisis (Yodzis, 1981; Ives & Carpenter, 2007).
91	Despite decades of research on food web stability, the topic is still highly
92	debated, especially concerning whether higher biodiversity confers higher resilience to

93	disturbance (Hatton et al., 2024; McCann, 2000). While classic theories emphasise the
94	destabilising role of diversity given a higher connectance among multiple nodes
95	increasing chances of cascade extinctions (May, 1973), contemporary theory suggests
96	a stabilising role of diversity when this is associated with weak interactions among
97	predators and multiple prey, creating negative covariance between different resources
98	buffering the system against extinctions (McCann, 2000). Despite the large and
99	growing body of theoretical studies on these ideas, empirical evaluations are still
100	lagging behind, as appropriate and detailed data for rigorously testing these
101	theoretical advances are not widely available (Ives & Carpenter, 2007).
102	Describing food webs in streams and rivers is particularly challenging due to the
103	inherent complexity and dynamics of these ecosystems (Winemiller, 1990). The
104	continuous flow of water combined with the spatio-temporal heterogeneity of
105	resources create a constantly changing environment, making it difficult to capture the
106	food web in full detail. Tropical streams particularly pose a challenge as they are highly
107	diverse and knowledge of trophic interactions is rare for many taxonomic groups
108	(Motta & Uieda, 2005; Reboredo Segovia et al., 2020), resulting in few isolated food
109	web descriptions (Ceneviva-Bastos et al., 2012; Motta & Uieda, 2005) that we know
110	little about their stability in the face of disturbance. Among these understudied
111	ecosystems, streams of Brazilian Atlantic Rainforest are highly threatened by human
112	land-use intensification and the substitution of forests for pasture and monoculture
113	plantations (Siqueira et al., 2015). Since these ecosystems provide a myriad of services
114	to human society, from fresh water and recreation to nutrient cycling (Meyer, 1997;
115	Palmer et al., 2014), understanding the stability of their food webs in well-preserved

regions is the first step in predicting their response to human impacts (Collyer et al.,2023).

118 Importantly, tropical stream ecosystems are likely to differ in their structure 119 and functioning compared to their better-studied temperate counterparts (Saito, 120 Perkins, et al., 2021). In terms of food webs, warmer tropical streams should be 121 composed of species with fast life cycles, accelerated biomass turnover, and lower 122 local densities (Saito, Stoppa, et al., 2021), resulting in highly variable composition 123 (Sigueira et al., 2020) and species interactions (Saito, Perkins, et al., 2021). A recent 124 study hypothesised that such highly dynamic food webs, embedded in a high regional 125 diversity, should be stable due to the weak interaction effects among multiple 126 interacting species (Collyer et al., 2023), where the functioning of a diverse, generalist 127 community would be buffered against disturbances by interchanges of trophic 128 interactions (Kratina et al., 2012; Rooney & McCann, 2012). In that case, we should 129 expect pristine tropical stream food webs to depict two patterns. First, local food webs 130 should be composed of predator-prey interactions that deviate from optimal predator-131 prey mass ratios (Collyer et al., 2023; Kratina et al., 2012). Aquatic food webs are 132 commonly size-structured, meaning that predators are consistently and systematically 133 larger than their prey, and yet, under warmer tropical conditions, we should have a 134 higher prevalence of omnivory because high energetic demands can force organisms 135 to feed up and down the food web (González-Bergonzoni et al., 2012). Therefore, we 136 hypothesise that pristine food webs will be composed of weakly size-structured 137 interactions, with predators feeding on both large and small prey due to their high 138 metabolic requirement. Second, these tropical food webs should also be characterised 139 by high local diversity, buffering predators from extinctions due to the possibility of

140 prey switching and stabilising dynamics between resources. Since these tropical 141 communities are prone to random variations in composition (Sigueira et al., 2020), a 142 high diversity of possible interactions should enhance the stability of these systems, as 143 redundant predators and prey can buffer the system against the loss of energetic 144 channels. 145 In addition, local food webs are always exchanging energy and matter within a 146 regional meta food web (Winemiller, 1990). As such, the realisation of potential 147 trophic interactions is constrained by the dispersal processes of predators and prey 148 (Rooney & McCann, 2012; Winemiller, 1990). Similar to the role of predators 149 dampening variation at the bottom of food webs (Rooney & McCann, 2012), mobile 150 predators coupling sub-food webs can stabilise metacommunities by buffering 151 variability among communities (Rooney et al., 2008; Sigueira et al., 2024). This should 152 increase spatial asynchrony among communities entailing high food web dissimilarity 153 in space, mostly due to changes in predator frequency. Considering the expected high 154 local dynamism of Atlantic Forest stream communities due to faster metabolism, we 155 hypothesise a high dissimilarity of local food webs in space, being stabilised by 156 predator coupling at the regional scale (Rooney et al., 2008). 157 Despite the dozens of methods developed to characterise food webs in nature, 158 the use of individual methods to estimate trophic interactions commonly results in 159 incomplete or simplified characterizations (Layman et al., 2012). Fortunately, the 160 combination of recent theoretical and methodological advances gives us new tools to 161 describe patterns of energy fluxes at the population level with high precision. First, a 162 new method unifying multiple sources of information within a singular analytical 163 Bayesian framework provides an excellent opportunity to untangle undescribed food

164	webs, while overcoming problems of individual sources of information (Hernvann et
165	al., 2022). This method integrates information taken from the literature, from direct
166	observations and extracted from stable isotope analyses to infer the most likely diet
167	proportion of each consumer and the likelihood of these interactions. Second,
168	advances in metabolic scaling theory allow us to infer the energy requirements of
169	populations based on their individual body masses and their total population sizes
170	(Brown et al., 2004). Together with information about diet proportions, we can now
171	estimate the required energy potentially flowing from prey to predators, quantifying
172	the food web in a general ecological currency (Gauzens et al., 2019).
173	Leveraging a suite of advances in food web ecology, we evaluate how stable
174	the pristine ecosystems of the Brazilian Atlantic Rainforest should be in face of
175	disturbances. We first characterise a well-resolved meta food web of streams from
176	Atlantic Forest through the integration of node properties (body mass and abundance)
177	and various sources of feeding link information. Second, we applied recent methods
178	for calculating the stability of the food web to disturbances within an energetic
179	framework (Gauzens et al., 2019; Moore & de Ruiter, 2012). We hypothesised that 1)
180	due to the elevated metabolic demands in warm conditions, invertebrates and fish
181	assemblages would be weakly size-structured, characterised by predators feeding at
182	multiple trophic levels, with with a weak association between individual body mass
183	and trophic level within invertebrate and fish assemblages, as well as across the whole
184	food web. 2) Given the high species diversity in tropical streams, we anticipated that
185	energy flow within the food webs would involve a multitude of links. Predators would
186	engage in a range of non-specialized interactions with prey resulting in bioenergetically
187	stable food webs (Kratina et al., 2012). 3) The simulated removal of individual taxa

188	from a complex tropical food web would not significantly disrupt its stability, as it
189	would not heavily rely on key strong interactions. 4) Finally, we expected that the
190	spatial variation in the composition of local food webs would be associated with
191	compositional changes in large predators, indicating that mobile predators enhance
192	spatial asynchrony among communities entailing regionally stable meta food webs
193	(Siqueira et al., 2024).
194	
195	METHODS
196	We sampled food web components (basal resources, invertebrate and
197	vertebrate consumers) in relatively pristine streams in Southeast Brazil. We then
198	applied a Bayesian framework to describe a regional meta food web and five individual
199	food webs integrating data from gut contents analysis, published studies and stable
200	isotope analysis of consumers and resources (Hernvann et al., 2022). Finally, we
201	applied an energetic model using body masses, energy efficiencies estimates and the
202	network topology to describe the amount of energy fluxes and the food web stability
203	(Gauzens et al., 2019).
204	
205	Field and laboratory protocols
206	We sampled five (2nd to 3rd orders) stream stretches within the Cananeia
207	catchment (state of São Paulo, Brazil) to collect high-resolution community data for
208	food web reconstruction. We sampled three streams (S1, S6 & S8) which were less
209	than 3 km apart, and in one stream (S8) we sampled three different stretches along an
210	altitudinal gradient (with 24, 45 and 88 metres of altitude). The vegetation at the
211	studied sites is predominantly formed by Ombrophilous Dense Atlantic Forest, mostly

212	well-preserved stretches and few sections of secondary forest (Schaeffer-Novelli et al.,
213	1990). The climate is humid subtropical (Alvares et al., 2013), with mean annual rainfall
214	above 2,200 mm (Schaeffer-Novelli et al., 1990). There are two main seasons:
215	summers (November - April) have mean air temperature of approximately 27° C,
216	whereas mild winters (May - October) have a mean temperature of approximately 22°
217	C. The five stream sites were sampled in October 2019 and had a mean water
218	temperature of 22°C (SD=0.68), pH of 5.7 (SD=0.66) and oxidation-reduction potential
219	(mv) of 381 (SD=111) (see Table S1).
220	The field protocol encompassed standard sampling techniques for surveying
221	stream food webs. First, we performed 3-pass quantitative depletion electrofishing at
222	each site (up to 100 m) using a Smith-Root LR-24 backpack electrofisher with the
223	boundary of survey reaches enclosed by stop nets. We identified most captured fish to
224	species level and measured (fork length) in the field (SISBIO ethical approval number
225	72482-1). We sampled macroinvertebrates (>250 μ m) using 10 replicate Surber
226	samples (30 cm X 30 cm) randomly positioned in the stream benthos. We sorted these
227	samples live at the host laboratory using a transilluminated tray and identified them to
228	the lowest possible taxonomic level without preparing slices (e.g. Chironomidae were
229	identified to family level). We took measurements of individual linear dimensions (e.g.
230	head-capsule width or body length) with a calibrated ocular micrometre allowing
231	individual dry mass to be calculated from published regression equations (Collyer et

al., 2023). We sacrificed a subsample of all captured fish (n = 142) and fixed them in

233 99,3% Isopropyl alcohol for subsequent gut content analysis in the laboratory. We

extracted guts and examined under a stereomicroscope (Leica EZ4, 40x maximum

magnification). We identified all diet items found (n = 502) to the lowest possible
taxonomic level (28 categories).

237 During fieldwork we also collected material for subsequent stable isotope 238 analysis (SIA). We obtained fish tissue from fin clips for a subset of individuals of each 239 species caught during electrofishing surveys. We performed kick net sampling 240 qualitatively in all microhabitats (mostly gravel and boulder riffles and some leaf litter 241 pools) to collect macroinvertebrates which were processed whole for stable isotope 242 analysis. We sampled basal resources from each stream by collecting allochthonous 243 leaf packs, mosses attached to the substrate and scrapes of biofilm from stones and 244 boulders. We froze all samples in the host laboratory in liquid nitrogen (at -80 °C) in 245 individually labelled tubes until subsequent analysis. Back to the laboratory, we stored 246 all samples at 60° C in an oven until total dry mass was achieved. We grinded the 247 tissues to a fine powder. Subsequently, 1 mg +/- 0.2 mg of fish and macroinvertebrate 248 samples, and 2.5 mg ±0.2 mg of basal resources were weighed into tin capsules 249 (Elemental Microanalysis[®] 8×5mm) prior to isotopic analysis. For small invertebrate 250 taxa that potentially weighed less than 1 mg individually (e.g. Chironomidae, 251 Simuliidae), we pooled 6-20 individuals of similar size together to reach the minimum 252 weight expected for each sample (Perkins et al., 2018). We analysed samples of 253 macroinvertebrates (n=139), fishes (n=160) and basal resources (n=30) for carbon 254 $(\delta_{13}C)$ and nitrogen $(\delta_{15}N)$ stable isotope ratios at an analytical laboratory at Queen 255 Mary University of London, UK using a continuous flow isotope ratio mass 256 spectrometer (SerCon Integra 2, Stable Isotope Analyser, Crewe, UK). Protein IRMS 257 Standard (Elemental Microanalysis® OAS/Isotope 5g) encapsulated like the other 258 samples was used as a standard and inserted in each run after every ten samples. We

259	then applied an ANOVA comparing the δ^{15} N of basal resources (biofilm, moss and
260	leaves) among stretches and found that they were not distinct (ANOVA, F = 0.35, P =
261	0.84) indicating that δ^{15} N baselines among stream sites were comparable.
262	
263	Food web reconstruction
264	We applied the Ecodiet approach to derive a well-resolved meta food web
265	(Hernvann et al., 2022). This Bayesian hierarchical model jointly considers three
266	sources of information: direct observations (e.g. gut content analysis) including the
267	potential proportion of different diet items, literature information describing putative
268	feeding links based on interactions described in other sites, and data from stable
269	isotope analysis, derived from a Bayesian mixing model to estimate the likelihood of
270	the interactions and the diet proportions inferred from the two first sources of
271	information. Here, we integrated data from the five stream sites including 329 δ^{15} N
272	and δ^{13} C values of basal resources, macroinvertebrates and fish; 502 diet items
273	identified from fish gut content analysis and; 226 potential feeding interactions for
274	Neotropical stream communities derived from a literature search including

275 bibliometric analysis of 52 references (see Supplementary Material). This hierarchical

276 model generated the probabilities of trophic links and provided the proportions of diet

277 items for each taxon. The key strengths of this framework included the quantification

of i) the reliability of individual published datasets (i.e. different values range between
0 and 1 depending on the methods used in a published study for each interaction) and
ii) the relative importance of gut vs. literature data to define the food web topology to

- be investigated in the mixing model. For this last comparison, a parameter was set to
- 282 define how equivalent literature and gut content data are (e.g. setting the parameter

value to 50 indicates that literature data are equivalent to analyses of 50 new stomach
contents). In our case, all studies in the literature search were set to 1 (reliable) and
the literature data were given equal weight compared to gut content data. We
assessed the performance of the model using Gelman-Rubin test of MCMC
convergence. Variables (links) with Rhat > 1.1 failed to converge and we removed them
from the model. This method was implemented using the Ecodiet package in R
(Hernvann et al., 2022).

290 Using the estimated food web topology and the diet proportions, we applied 291 the fluxweb approach, which infers the amount of energy flowing through each 292 population considering a steady-state system (Gauzens et al., 2019). This method was 293 applied to both the meta food web and each of the five individual food webs. The 294 approach requires the average species body mass and population density information 295 to estimate the total biomass of each population and their energetic requirements. 296 The fluxweb method considers a top-down perspective where the energetic 297 requirement of each consumer species is calculated from the mean body mass of that 298 species, and its population density, balanced against the population biomasses of their 299 prey. In this balanced system, gains G_i are balanced with losses L_i which are calculated

300

as

301
$$L_i = X_i + \sum_i F_{ij}$$
, (eq. 1)

where X_i defines species losses (e.g. metabolic costs or death rates) and F_{ij} is the flux of
energy from species *i* to predator *j*. In this case, gain G_i is defined as

$$G_i = \sum_i F_{ji} e_{ij}, \qquad (eq. 2)$$

305	where F _{ji} defines the influx coming from other species depending on a diet proportion
306	(estimated with Ecodiet in our study) and $_{\mathrm{e}_{ij}}$ denotes the efficiency in energy uptake
307	given the prey identity (see below). In our study, the metabolic cost χ_{i} was defined
308	from the allometric equations (Brown et al. 2004)
309	$X_i = X_0 M_i^b$, (eq. 3)
310	where χ_0 and <i>b</i> are constants related to organismal physiologies and M_i is a given body
311	mass. We defined χ_0 equal to 18.18 for fishes, 17.17 for invertebrates, and b equal -
312	0.29 for all organisms following Brown et al. (2004). Efficiencies were defined at prey
313	level and set to 0.906, 0.545 and 0.158 for animals, plants and detritus, respectively
314	(i.e. consumers feeding on animals have higher efficiencies per unit of mass consumed)
315	(Gauzens et al., 2019). We additionally applied different values for <i>b</i> and efficiencies to
316	understand the sensitivity of our analyses to specific input parameters. For the
317	metabolic exponent b, we considered the values from a review of metabolic rates
318	across organisms and ontogenetic development (Glazier, 2005). In this study he
319	identified that metabolic rate exponents are commonly 3/3, 3/4 and 1 (isometric scaling).
320	Therefore, to consider such variation we also used the values of <i>b</i> considering these
321	three different exponents. For the efficiency values, we considered the minimum and
322	maximum values of the 95% confidence interval modelled in a systematic assessment
323	of efficiencies and respiration in natural communities (Lang et al., 2017). In this
324	assessment, they found that carnivores had the highest assimilation efficiency
325	(ε0,carnivores = 0.906, Cl 0.95 = 0.88-0.927), herbivores had an intermediate
326	assimilation efficiency (ϵ 0,herbivores = 0.545, Cl 0.95 = 0.466-0.621), and detritivores
327	had the lowest assimilation efficiency (ε0,detritivores = 0.158, CI 0.95 = 0.108-0.227).
328	

329 Data analysis

330 Hypothesis 1: Due to the elevated metabolic demands in warm conditions, tropical food

331 webs should be weakly size-structured, with variable size differences between

332 predators and prey.

333 To test our first hypothesis and to determine the relationship between body 334 mass and trophic position, we related δ^{15} N tissue values (a proxy for trophic position) 335 and body mass by applying linear mixed effects models for the isotopic values of 336 consumers. Log-transformed mean consumer body mass (mg of dry mass) was treated 337 as a fixed effect while taxonomic identity was treated as random intercept and random 338 slope, separately. We also ran models that included the group (fish or invertebrate) as 339 a fixed effect with interaction with body mass to account for a potential relationship 340 that is dependent on the organism group. We could not apply a single model with both 341 random intercept and slope due to the large number of samples and taxa in our 342 dataset (lack of sufficient degrees of freedom). Models with and without organism 343 group as a fixed effect were compared based on their marginal R², AIC, and a Chi-344 Squared test.

345 We then determined size-density relationships regressing species' mean body 346 mass and population density on double-log axes. These relationships depict how 347 energy is shared among species with different body masses, providing information 348 about species that have higher or lower densities than expected based on allometric 349 scaling principles (White et al., 2007). We applied this method for the meta food web 350 and each of the five individual food webs. These empirical relationships were 351 contrasted against the theoretical allometric expectation considering a slope of -1, or 352 Sheldon's rule that considers that despite the scaling of -¾ of metabolic rates with

353 increasing body sizes, there are consistent energetic losses among trophic levels

354 (Brown et al., 2004). Therefore, a theoretical relationship with slope-1 for the best-fit

355 model (we found the intercept considering minimum least-square criteria) was fitted

356 together with the empirical linear model.

357

358 Hypothesis 2: Given the high species diversity in tropical streams, energy flow within
359 food webs would be characterised by weak interactions between predators and prey
360 resulting in bioenergetically stable food webs.

361 To test this hypothesis, first, we characterised the meta food web and each 362 individual food web by calculating the number of nodes (number of taxa in each food 363 web), number of links (number of trophic interactions), link density (mean number of 364 links per node), connectance (the ratio between the number of links and all possible 365 links), compartmentalization (measures the degree of connectedness of subsystems 366 within a network, with higher values of connectance indicating more discrete 367 subsystems), mean trophic position (mean trophic position of nodes within a food web 368 with basal resources set to 1) and omnivory (the mean degree of variation in the 369 trophic position of consumed resources) (Kones et al., 2009; Kratina et al., 2012; 370 Latham, 2006; Pimm & Lawton, 1980). Indices were calculated using the package 371 NetIndices in R (Kones et al., 2009). 372 Then, we tested the hypothesis by using the estimated energy fluxes from the 373 fluxweb analysis and calculating the stability of food webs (stability of their Jacobian 374 matrices) considering a Lotka-Volterra model of consumers and resources (Moore & de 375 Ruiter, 2012). The stability of a food web can be measured using a Jacobian interaction

376 matrix concerning the partial derivatives of the equations for each species with respect

to all species in the food web near equilibrium (May, 1973; Neutel et al., 2002). A food
web is therefore considered stable when the Jacobian matrix has negative real parts
eigenvalues for every interaction - i.e., all consumers can be sustained based on the
biomasses of their resources (see Supplementary Material from Gauzens et al. 2019).

382 Hypothesis 3: Local extinctions of individual taxa from a complex tropical food web
383 would not significantly disrupt its stability, as it would not heavily rely on key strong
384 interactions.

385 To test the third hypothesis, we simulated multiple species extinction scenarios 386 to determine the consequences of individual species loss for the stability of the meta 387 food web. Here, in each scenario we individually removed one species at a time, 388 recalculating energy fluxes and stability using fluxweb in R (Gauzens et al., 2019). We 389 performed this species removal procedure for all species in our meta food web. 390 Secondary extinctions could happen in our model after species removal, if a given 391 species has a positive eigenvalue in the new Jacobian matrix after calculating stability. 392 In this case, the food web would be termed unstable. To understand which network 393 aspect is associated with higher food web stability, we calculated the network indices 394 described above (number of taxa in each food web, number of links, link density, 395 connectance, compartmentalization, mean trophic position, and omnivory) for each 396 simulated food web after each species extinction. With these values, we applied a 397 Pearson correlation matrix between them with the inclusion of the maximum 398 eigenvalue of the Jacobian matrices (the stability measure).

399

400	Hypothesis 4: Spatial dissimilarity of local food webs would be associated with changes
401	in large predators, indicating that mobile predators enhance spatial asynchrony among
402	communities entailing regionally stable meta food webs.
403	To test the last hypothesis we calculated compositional and network
404	dissimilarity using the Bray-Curtis index (Legendre, 2014). Whereas the compositional
405	dissimilarity is based on differences in the relative species abundances, the network
406	dissimilarity also accounts for the presence or absence of species interactions
407	following species addition - e.g. one species can add multiple interactions to a food
408	web, while another species can add only one interaction. We decomposed the network
409	beta diversity into the components of 'changes caused by the absence of predator',
410	'changes caused by the absence of prey', or 'changes caused by mutual absences'
411	(Novotny, 2009). We did not calculate the components of network dissimilarity
412	associated with rewiring and turnover, as our interactions are defined at the meta food
413	web level, preventing our assessment of rewiring - i.e. species always interact with the
414	same species once they are present. Beta diversity indices were calculated using the
415	bipartite package (Dormann et al. 2008).
416	
417	RESULTS
418	Food web components
419	We identified 1352 invertebrates from 54 different taxonomic groups. From

420 this, 313 individuals were *Macrobrachium* (Paleomonidae, Decapoda) collected

421 through both Surber sampling and electrofishing, while the others mostly included

422 insects, with a small proportion (<1%) of Oligochaeta, Platyhelminthes and Gastropoda

423 collected by Surber sampling (0.9 m² in total). The insects with the highest abundances

424	were <i>Macrostemum</i> (Hydropsychidae, Trichoptera, n = 170), <i>Gripopteryx</i>
425	(Gripopterygidae, Plecoptera, 118), Simulium (Simuliidae, Diptera, 95), Chironomidae
426	(Diptera, 92), Chimarra (Philopotamidae, Trichoptera, 79), Smicridea (Hydropsychidae,
427	Trichoptera, 60), Helicopsyche (Helichopsychidae, Trichoptera, 46), Farrodes
428	(Leptophlebiidae, Ephemeroptera, 30), Baetidae (Ephemeroptera, 26) and
429	Belostomatidae (Hemiptera, 20). We also captured 332 fish from 12 species (413,5 m ²
430	sampled). Two fish species were found across all sites: catfish Acentronichthys leptos
431	Eigenmann & Eigenmann, 1889 (66), and knifefish Gymninotus pantherinus
432	Steindachner, 1908 (32). Other abundant (but less widespread) fish species included
433	the lambari Deuterodon iguape Eigenmann, 1907 (71) and the characids Hollandichthys
434	multifasciatus Eigenmann & Norris, 1900 (61), Characidium Ianei Travassos, 1967 (34)
435	and Mimagoniates microlepis Steindachner, 1877 (34).
436	
437	Relationship between trophic position and body mass

438 We analyzed 329 samples for stable isotopes that were categorized into 42 439 groups, including basal resources, macroinvertebrates and fish. Fish generally has the highest δ^{15} N values (i.e. occupied the highest trophic positions), but there was a 440 441 considerable overlap with many macroinvertebrates and shrimps. The relationship 442 between δ^{15} N and individual body masses suggested that fishes are more strongly size 443 structured than macroinvertebrates, only partly supporting our first hypothesis (Figure 444 1B). Macroinvertebrates had high isotopic variability with large overlap in bi-445 dimensional space between species with different body masses (Figure 1C), although 446 some taxa were clearly distinct (e.g. *Macrobrachium* and damselflies with high $\delta^{15}N$ 447 values and grazers *Psephenus* and *Gripopteryx* with the lowest $\delta^{15}N$ values). Our mixed

Journal of Animal Ecology: Confidential Review copy

448	effects models supported this visual inspection with models with both random slopes
449	and intercepts (species) returning associations with body sizes (estimate = 0.45 , SE =
450	0.08, t = 5.38 and estimate = 0.39 SE = 0.08, t = 4.57, respectively) that depended on
451	the group (fish or invertebrate) (interaction effect, estimate from model with random
452	slope = -0.31, SE = 0.11, t = -2.86 and estimate from model with random intercept = -
453	0.27, SE = 0.11, t = - 2.47). Overall, this means that there is a general association
454	between trophic level and body sizes, where fishes are strongly size structured, but
455	invertebrates are not. Considering groups as a fixed effect interacting with body size is
456	important for the relationship as a comparison with a model without groups renders
457	only half of the marginal R^2 (marginal R^2 = 0.64 vs. marginal R^2 = 0.31) and a
458	significantly higher AIC (AIC = 788 vs. AIC = 802, Chi square = 17.33, P < 0.001).
459	Moreover, separate models for only fish and only invertebrates return significant
460	slopes only for fish (body mass fixed effect estimates = 0.60, SE = 0.09, t-value = 6.44,
461	species as random slopes). The patterns in community-level isotopic composition for
462	individual sites were largely similar to those observed for the regional meta food web
463	(Figure S1).

465 Figure 1. Isotopic composition of fish and macroinvertebrates from Atlantic Forest 466 streams (Cananeia, Brazil). a) General association between mean body mass (mg) and 467 δ^{15} N values (relative trophic position) of organisms (some isotopic samples encompass 468 multiple individuals, e.g. Chironomidae). Individual associations for fish (b) and 469 invertebrates (c). Ellipses correspond to 95% confidence level for a multivariate t-470 distribution. The line in the (a) panel indicates the fitted linear mixed effects model 471 with body mass as fixed effect and species as random slope (estimate = 0.45, SE = 0.08, 472 t = 5.38). The model in the fish panel indicates the fitted linear mixed effects model 473 with body mass as fixed effect and species as random slope (body mass fixed effect 474 estimates = 0.60, SE = 0.09, t-value = 6.44).

475

476 Food web construction

477 The EcoDiet model identified a high link probability for most of the analysed 478 interactions with link probabilities within two groups: 14% had probabilities between 479 0.2 and 0.18, but all the other 86% had probabilities higher than 0.82. The diagnostics 480 of the whole model resulted in Gelman-Rubin statistics higher than 1.1 for 54 links 481 (~16% of the links), indicating a lack of convergence in the MCMC algorithm (Hernvann 482 et al. 2022). The final meta food web after removing these links contained 307 links, 483 including the likelihood of diet proportion for each consumer. The number of nodes in 484 each site ranged between 28 and 41 while the number of interactions ranged between 485 73 and 171, with a positive trend between the two characteristics - more diverse sites 486 had more links and also occurred in wider and shallower stretches of streams (e.g. S1 487 and S8C). Consequently, connectance was similar between stretches with a mean of 488 10% of all possible links actually realised (see Table S2 for other network metrics). 489 490 **Energy fluxes** 491 For the meta food web, the 10 populations with highest energetic demands

492 were composed of six Trichoptera genera Macrostemum, Leptonema, Synoestropsis,

- 493 Helicopsyche, Cernotina and Phylloicus, one Ephemeroptera (Campsurus), one Diptera
- 494 (Chironomidae), one Plecoptera (Gripopteryx) and one Palaemonidae
- 495 (Macrobrachium). In sum, these species account for 70% of total energy flux in these
- 496 ecosystems. Yet, a considerable 30% of the energy flow is shared between the
- 497 remaining 48 consumers, which is partially in agreement with the second hypothesis
- 498 (Figure 2). The biofilm was the main basal resource that mostly contributed to food
- 499 web energy flows, followed by moss and leaves (Figure S3).
- 500

507	7
-----	---

508	Some invertebrates (e.g. Macrostemum, Macrobrachium) were
509	disproportionately abundant (Figure 3). The relationship between body mass and
510	population density showed that these taxa tended to be regionally more abundant
511	than expected from their mean body masses (i.e. they were above the regression
512	model, Figure 3), especially compared to the empirical model, but also to the
513	theoretical expectation with slope = -1. This pattern was also evident at the local scale,
514	but the species above the regression model varied from site to site (Figure S2).
515	Moreover, the empirical relationship was shallower than the theoretical expectation
516	with exponent -1

518

Figure 3. Species size-density relationship for Cananeia streams (density relationship
 for the regional meta-web). Log-transformed density of individuals in the regional

for the regional meta-web). Log-transformed density of individuals in the regiona
 species pool is regressed against log-transformed mean body masses of each

522 taxonomic group (slope = -0.45, R² = 0.48, P < 0.001). Species above or below the

523 524 525 526	regression line indicate species with relatively more or less individuals than expected based upon their body size. The dashed line indicates the least-square best fit model for a slope=-1, an empirical benchmark predicted by allometric scaling theory.
527	For individual stream sites, some species were important contributors across
528	all sites while some of them were only important for some specific ones (Figure 4). For
529	instance, Macrostemum, Chironomidae, Gripopteryx and Macrobrachium were
530	widespread and abundant in the regional species pool and contributed strongly to the
531	energy flux in all five stream food webs. In contrast, Campsurus, Farrodes, Deuterodon
532	iguape, Helicopsyche, Macrelmis and Synoestropsis were only important in one or two

533 sites (Figure 4).

Figure 4. Energy fluxes (J/year/m²) from individual nodes and the five food webs from
Atlantic Forest streams from Cananeia (São Paulo, Brazil). Position along the y axis in
the individual food webs represent the trophic position of each taxon. Darker link
colours represent interactions of higher energy fluxes.

539

540 Besides these differences among individual food webs, supporting our second 541 hypothesis, all food webs and the meta food web were stable, i.e. had negative values 542 for the maximum eigenvalue of the Lotka Volterra Jacobian matrices. This analysis 543 considered that stream food webs are in a stable state if the real parts of eigenvalues 544 from the Jacobian are all negative (between -4.9 and -13.5). This means that the 545 population energy demands are consistent with the amount of energy available at lower trophic levels, meaning that there is no population too large that cannot be sustained by the amount of energy from prey. The sensitivity analyses, changing the values of *b* and efficiencies, also returned stable meta food webs in except for when *b* = 1, which is the isometric scaling where metabolic rate is constant. The results of the sensitivity analyses can be found in Supplementary Material and the results using the original values of *b* (-0.29) and mean efficiencies from Lang *et al.* (2017) are reported in following.

553 In agreement with our third hypothesis, the simulation extinction resulted in 554 food webs that remained stable after the removal of individual species each at a time 555 (maximum Jacobian eigenvalues ranging between -14.60 and -7.41). That is, after 556 species removal, no secondary extinctions were observed (all species had negative 557 eigenvalues after calculating stability in the resulting food webs). We found that, 558 despite the consistent stability of the food web to species removal, and lack of secondary extinctions, there are network patterns associated with the variation in the 559 560 stability values (Figure 5). Higher stability (the inverse of the maximum eigenvalue) was 561 related to greater omnivory in the food web (r=0.27, p<0.05), lower levels of network 562 compartmentalization (r=-0.32, p<0.05), and lower average link weights (r= -0.40, 563 p<0.05) (Figure 5 and Figure S4). Thus, removing omnivorous species that connect 564 different sub-webs with multiple weak interactions is detrimental to ecosystem 565 stability. When looking into the species that have the highest impact on food web 566 stability, we can also observe that many fish species were of high importance, 567 especially considering how little they contribute to the total energy fluxes (e.g. the 568 knifefish Gymnotus pantherinus that eats 22 different food items and the tetrafish 569 Deuterodon iquape with 19 food items, Figure 5).

570

571 Figure 5. Associations between the stability of simulated meta food webs and network 572 metrics. Each point in each scatterplot represents a simulated meta food web after the 573 extinction of a given species (labelled). The stability was estimated as the maximum 574 eigenvalue of the Jacobian matrix using a Lotka-Volterra system of equations. More 575 negative values indicate higher system stability to disturbances. Lower stability was 576 associated with simulations that reduced omnivory and increased 577 compartmentalization and average link weight. The models in each plot represent linear regressions with the following results: Omnivory ($R^2 = 0.07$, P = 0.04), 578 Compartmentalization ($R^2 = 0.10$, P = 0.01), Average link weight ($R^2 = 0.15$, P = 0.001). 579 580

581 Food web dissimilarity

582 As predicted by the fourth hypothesis, the dissimilarity of the network was

- 583 higher than the compositional dissimilarity (Figure 6). Approximately 40% of
- 584 interactions changed from one food web to another, while pure compositional
- 585 dissimilarities among stream communities were approximately 25%. These
- 586 compositional changes were strongly associated with the absence of predators when
- 587 prey taxa were present, with a much smaller contribution of the component of prey
- absence and mutual absence (less than 10%, Figure 6).

Figure 6. Compositional and network dissimilarity among local streams from the
Cananeia watershed (São Paulo, Brazil) based on Bray-Curtis index. Composition =
compositional beta diversity, Network = network beta diversity, Network predator =
network dissimilarity caused by the absence of predator, Network prey = network
dissimilarity caused by the absence of prey, Network both = network dissimilarity
caused by the absence of both predators and prey.

597 DISCUSSION

598	Untangling a network of trophic interactions through integration of energetic
599	principles has been proposed as a key new approach to understand ecosystem
600	functioning under a comparable currency (Barnes et al., 2014). Here, we combined
601	recently advanced methods and theories (Gauzens et al., 2019; Hernvann et al., 2022)
602	to derive a well-resolved energetic food web from tropical rainforest and investigate
603	the mechanisms behind its stability. By doing so, we found locally and regionally stable
604	networks, where energy was channelized through a taxonomically diverse set of
605	organisms, such as chironomids and stoneflies, and from small to large taxa (e.g. from
606	chironomids to palaemonid shrimps). These food webs were stable in the face of

simulated individual species extinctions with an evidenced importance of omnivorous
fishes interconnecting different food web compartments at local scales and different
communities at regional scales. These characteristics potentially govern food web
stability at local and regional scales highlighting the roles of omnivory and alpha and
beta diversity. Below, we explain these new insights for understanding the dynamics of
tropical stream ecosystems and how important these mechanisms could be for
anticipating the impacts of the current environmental crisis.

614 The relationship between organism body mass and their trophic position 615 provides a measure of food web size structure (i.e. the extent to which larger 616 consumers feed on small prey and whether this is at a constant ratio) (Perkins et al. 617 2021). Partially in contrast to our first hypothesis, there was a strong association 618 between δ^{15} N values and body mass for fish, both within and across species, indicating 619 that larger fish are commonly higher up the food chain. This suggests that fish 620 predators interact within a well-defined prey size spectrum to fulfil their energetic 621 demands, a pattern expected in simple food web compartments comprising only a 622 limited number of functional groups (Keppeler et al., 2020). However, this pattern did 623 not hold for invertebrates where there was no relationship, more in agreement with 624 our second hypothesis. This lack of association indicates that invertebrate consumers 625 feed plastically up and down the food web to meet their metabolic requirements (i.e. 626 feeding on larger or smaller prey than expected based on their optimum predator-prey 627 mass ratio, (Potapov et al., 2021). It has been suggested that tropical streams have a 628 greater prevalence of omnivorous and generalist feeding than in their temperate 629 counterparts that have proportionally more taxa from delimited trophic groups like 630 shredders and obligatory predators (Boyero et al., 2011). This generalist feeding

strategy decreases energy transfer efficiency along the food chain due to a decrease in
net gains when feeding upon proportionally small or large prey (Brose et al., 2005;
Stephens & Krebs, 2019). Our findings add mounting evidence that generalist
macroinvertebrates at intermediate trophic positions are likely inefficient, but
represent diverse conduits of energy that potentially enhance the stability of these
complex systems (Collyer et al., 2023).

637 At the meta food web scale, 70% of the total energy flux depended on a subset 638 of ten taxa spread over orders of magnitude in body masses (from chironomids with an 639 average 0.2 mg per individual to large shrimps with an average of 1060 mg per individual). This may have consequences for the stability of the food web as different 640 641 body masses are associated with differences in life cycles and environmental 642 responses such as size-selective predation, size-related risks of dislodgement by 643 hydraulic forces, and use of size-related refugia in streambeds to counter these risks 644 (Woodward et al., 2005). Indirectly, body mass is closely related to other traits, with 645 smaller species often exhibiting population resilience with short life cycles, rapid 646 growth, high reproductive rates and high number of dispersal events in time (Brown et 647 al., 2004; Saito et al., 2015). We hypothesise that having a set of invertebrates with a 648 wide range of body masses contributing strongly to energy flow could enhance 649 resilience to local perturbations in tropical streams. Environmental changes negatively 650 affecting specific size classes could be compensated by organisms with different body 651 masses, which could sustain energy flows through the food webs. 652 Despite the subset of macroinvertebrates that were important for energy flows 653 in all five streams, some taxa were only important in one or two sites. This diverse set

of taxa constituted approximately 30% of the total energy flow, regionally. Moreover,

655 three key results highlight the importance of the local and regional diversity for the 656 functioning of tropical stream food webs, where energy flows do not rely strongly on 657 specific trophic interactions. First, we found that simulating individual extinctions did 658 not destabilise the meta food web, nor caused any immediate secondary extinctions. 659 However, there were associations between more stable food webs and higher 660 prevalence of omnivory, weaker trophic interactions and lower compartmentalization. 661 Altogether this is a direct support that omnivorous species that connect multiple 662 compartments with weak interactions are key in sustaining stable food webs (Kratina 663 et al., 2012). As such, we indeed found that some fish species are relatively more 664 important for the maintenance of food web stability, which is interesting as this 665 describes different roles a species can have in the food web. On one hand, a species 666 can contribute highly to the total energy flux and productivity linking terrestrial and 667 aquatic compartments through the emergence of adults, while not being strongly 668 pivotal for the network stability (e.g. Chironomidae). On the other hand, proportionally 669 low amounts of energy can flow through other species, but these may connect 670 different food web compartments, allowing for higher ecosystem resilience o (e.g. 671 omnivorous fish that connect basal resources, macroinvertebrates and other fish). 672 Second, local food webs were approximately 40% dissimilar among each other. 673 A high regional diversity coupled with high spatial variation can assure that multiple 674 species can contribute a little to the energy flow, but also that a diverse pool of 675 potential colonisers would be able to compensate for the eventual loss of species. 676 Indeed, we found that several size classes were regionally composed by multiple taxa 677 that could potentially compensate for species losses. For instance, Macrostemum (a 678 net-spinning caddisfly) is the main contributor to energy fluxes, that regionally have at

679 least three other genera from the same family with fairly similar sizes co-occurring in 680 the watershed on different densities (Leptonema, Macronema, Smicridea). Intriguingly, 681 Leptonema and Smicridea were found to be the most abundant taxa in the presence of 682 Macrostemum in other well preserved Atlantic Forest streams (Saito, Stoppa, et al., 683 2021; Siqueira et al., 2020). Tropical stream communities have been suggested to be 684 more stochastic in terms of colonizations and demography in comparison to temperate 685 systems due to an accelerated pace of life that leads to more dispersal events and 686 smaller population sizes (Saito, Perkins, et al., 2021; Siqueira et al., 2020). The greater 687 contribution of stochastic processes should render spatial and temporal variation in 688 the relative abundance of these taxa but with potentially weak impacts for patterns of 689 energy flow.

690 Third, the dissimilarity of the food webs were associated to changes in 691 predators, rather than prey, suggesting that spatial asynchrony of mobile predators 692 dampens variability of prey communities and stabilises food webs regionally. We found 693 that most of the fish species sampled were only present in one or two sites out of five, 694 while most of the smaller invertebrates were common in four to five sites. Together 695 with the importance of omnivorous fish evidenced by our extinction simulations, we 696 can outline a regional effect of fish beta diversity in the stability of food webs. This 697 should happen because omnivorous fish should feed upon productive patches when 698 resources are high and move to other patches when resources get lower, allowing 699 recovery of resources (i.e. invertebrates) from low densities. As an example, the catfish 700 Rhamdia quelen, was one of the most important taxa for food web stability and was 701 found to move more than 300 m in two hours of observation, indicating that one 702 individual can effectively forage across multiple stream stretches within days (Schulz &

Leuchtenberger, 2006). This spatial asynchrony in the community of larger predators
within a metacommunity of small spatial extent and little environmental heterogeneity
suggests that these species could operate as mobile predators connecting the different
streams stabilising the meta-food web.

707 Despite the evidence outlining the mechanisms supporting the stability of 708 tropical stream food webs, we describe two key limitations of our work. 1) Our study 709 was conducted in one tropical region using five individual food webs composing one 710 meta food web and therefore, we do not have a strong empirical gradient to test the 711 influence of variations in species diversity, omnivory and beta diversity on stability 712 patterns. We emphasise the need for future studies to try to disentangle such effects 713 in studies comparing food webs across gradients using empirical data (e.g. across 714 latitude) or experiments (mesocosm experimentations). 2) Our modelling exercise took 715 into account the extinction of singular species and its potential effects on secondary 716 extinctions caused by the loss of energy sources and how this could echo to 717 destabilising the network. While accounting for realistic interactions in terms of energy 718 flow, our simulation could not account for known mechanisms associated with 719 secondary extinctions such as higher order interactions (Fowler, 2010) and behavioural 720 changes with predator release (Hammerschlag et al., 2022). We emphasise how our 721 study gives only the first steps in understanding tropical stream stability, as all these 722 complex responses could modify real food web responses. 723 In summary, we found that all five tropical stream sites have energetic food 724 webs that are stable to small perturbations. We observed two important associations:

1) diversity increases the total energy flowing up to the apex predators, 2) The

presence and beta diversity of omnivorous fish stabilises local and regional food webs.

727	These lead us to two important mechanisms for the functioning of tropical stream food
728	webs: (i) the diversity of body masses should buffer against size-dependent
729	disturbances allowing high rates of productivity with higher diversity and (ii) high
730	regional diversity and weak, non-specialized interactions buffering against local
731	stochastic variation in species composition. These two mechanisms critically depend
732	on the maintenance of local and regional biodiversity in tropical streams, which is
733	known to be strongly affected by human land use intensifications from forests to
734	monoculture plantations in different ways (Neves et al., 2023; Siqueira et al., 2015).
735	Therefore, an urgent challenge is to understand how the systematic loss of diversity
736	jeopardises the stability of stream food webs under human impacts and what could be
737	the consequences for a sustainable use of resources.

Sensitivity analyses

We applied the fluxweb approach, which infers the amount of energy flowing through each population considering a steady-state system (Gauzens et al., 2019). The fluxweb method considers a top-down perspective where the energetic requirement of each consumer species is calculated from the mean body mass of that species, and its population density, balanced against the population biomasses of their prey. In this balanced system, gains G_i are balanced with losses L_i which are calculated as

$$L_i = X_i + \sum_{i} F_{ij}, \qquad (eq. 1)$$

where χ_i defines species losses (e.g. metabolic costs or death rates) and F_{ij} is the flux of energy from species *i* to predator *j*. In this case, gain G_i is defined as

$$G_i = \sum_j F_{ji} e_{ij}$$
, (eq. 2)

where F_{ji} defines the influx coming from other species depending on a diet proportion (estimated with Ecodiet in our study) and e_{ij} denotes the efficiency in energy uptake given the prey identity (see below). In our study, the metabolic cost χ_i was defined from the allometric equations (Brown et al. 2004)

$$X_i = X_0 M_i^b, \qquad (eq. 3)$$

where χ_0 and *b* are constants related to organismal physiologies and M_i is a given body mass. In the main text, we defined χ_0 equal to 18.18 for fishes, 17.17 for invertebrates, and *b* equal -0.29 for all organisms following Brown et al. (2004). Efficiencies were defined at prey level and set to 0.906, 0.545 and 0.158

for animals, plants and detritus, respectively (i.e. consumers feeding on animals have higher efficiencies per unit of mass consumed) (Gauzens et al., 2019). Here, we present the results from sensitivity analyses applying different values for *b* and efficiencies. For the metabolic exponent *b*, we considered the values from a review of metabolic rates across organisms and ontogenetic development (Glazier, 2005). In this study, he identified that metabolic rate exponents are commonly $\frac{2}{3}$, $\frac{2}{3}$, and 1 (isometric scaling). Therefore, to consider such variation we also used the values of *b* considered the minimum and maximum values of the 95% confidence interval modeled in a systematic assessment of efficiencies and respiration in natural communities (Lang et al., 2017).

We observed stable meta food webs using the confidence interval of maximum and minimum efficiency during fluxweb calculations with the maximum eigenvalue of -23.8 for the minimum efficiencies and -16.19 for the maximum efficiencies. Therefore, we had no qualitative changes in our main conclusion of observing a stable meta food web in our studied system.

We found that the meta food web was insensitive to the variation in the *b* values, with negative maximum eigenvalues of the Jacobian matrices for exponents ³/₃ and ³/₄. When the scaling was isometric, meaning that metabolic rate is constant, the meta food web was unstable. This is because populations of larger individuals have higher energetic costs with isometric scaling and

therefore demand more energy flowing through the food web in comparison to situations with allometric scaling of metabolic rates with exponents <1. This was indeed the case in our meta food web as two of the largest fish species (*Rhamdia quelen* and *Synbranchus marmoratus*) had positive eigenvalues in the stability analyses and therefore cannot be sustained in the meta food web. As the isometric metabolic rate has been extensively demonstrated for pelagic, but not benthic organisms (Glazier 2005), we have little evidence that this is the most realistic scenario to represent our system.
