Abstract

Motion prediction is crucial for autonomous driving systems, as it enables accurate forecasting of future vehicle trajectories based on historical motion data. This paper introduces Trajectory Mamba, a novel efficient trajectory prediction framework based on the selective state-space model (SSM). Conventional attention-based models face the challenge of computational costs that grow quadratically with the number of targets, hindering their application in highly dynamic environments. In response, we leverage the SSM to redesign the self-attention mechanism in the encoder-decoder architecture, thereby achieving linear time complexity. To address the potential reduction in prediction accuracy resulting from modifications to the attention mechanism, we propose a joint polyline encoding strategy to better capture the associations between static and dynamic contexts, ultimately enhancing prediction accuracy. In addition, to balance between prediction accuracy and inference speed, we adopted a structure in the decoder that differs entirely from the encoder. Through cross-state space attention, all target agents share the scene context, allowing the SSM to interact with the shared scene representation during decoding, thus inferring different trajectories over the next prediction steps. Our model achieves state-of-the-art results in terms of inference speed and parameter efficiency on both the Argoverse 1 and Argoverse 2 datasets. It demonstrates a four-fold reduction in FLOPs compared to existing methods and reduces parameter count by over 40% while surpassing the performance of the vast majority of previous methods. These findings validate the effectiveness of Trajectory Mamba in trajectory prediction tasks.

1. Introduction

In the rapid development of autonomous driving technology [15], accurate motion prediction plays a crucial role

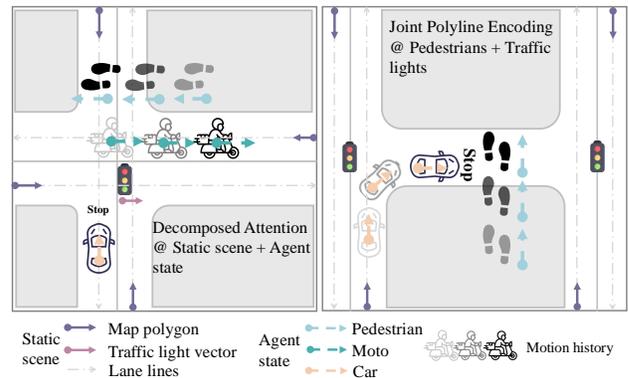

Figure 1. Illustration of proposed joint polyline encoding strategy, where we consider all factors that affect the movement of motor vehicles, jointly encoding pedestrians and traffic lights rather than categorizing the scene horizontally into static and dynamic context. Additionally, we decompose and encode the interactions between all agents and elements at each time step.

by forecasting future trajectories based on historical vehicle movement data. This task is not only vital for enhancing driving safety but also meets the stringent requirements for real-time system response. In recent years, learning-based approaches have been widely applied to motion prediction [4, 14, 27, 37, 38]. However, existing prediction methods often struggle to balance efficiency and accuracy, making it challenging to simultaneously meet performance and efficiency requirements in real-time applications. We attempt to analyze the underlying reasons from the following aspects and explore possible improvements:

(a). **Improving Prediction Accuracy:** In autonomous driving scenarios [36], there are numerous dynamic and static agents, and the diversity of this data presents significant challenges for motion prediction and model training. However, conventional methods [27, 37] often struggle to effectively fuse this heterogeneous data, particularly when it comes to integrating various features, which leads to sub-optimal prediction accuracy. On a positive note, factor-

ized attention-based transformers [19, 38] have made notable strides in decomposing heterogeneous data. However, these models often use a unified, horizontal approach when dealing with static scenes and dynamic agent features, and they fail to fully consider the deeper relationships between different scene elements and agent information.

(b). Enhancing Response Efficiency: Motion predictions are inherently recursive, implying that each prediction serves as an input for the next time step, leading to the progressive accumulation of errors over time. Notably, the advancement of sparse context encoding techniques [4, 33] has demonstrated significant potential in enhancing model efficiency. Nonetheless, prediction models based on attention mechanisms still face exponential growth in computational complexity and parameter size during recursive tasks due to inherent design constraints, which severely limit their efficiency and real-time capabilities in practical applications. Conversely, methods such as LSTM [16] are relatively more efficient, but numerous studies [18, 21, 34] have shown that they are incapable of achieving the predictive accuracy of transformer-based models.

In response, we propose an Attention-Mamba framework for motion prediction, termed Trajectory Mamba (Tamba), to overcome the limitations discussed above. First, we design a multimodal encoder-decoder architecture based on the state space model [8, 10, 25], comprising three parallel encoders and a decoder. By introducing a selective state space, we redefined the computation of the self-attention mechanism, enabling the model to selectively process input information by parameterizing the input of the state space model (SSM), thereby allowing the model to focus on or ignore specific inputs. Specifically, the selective state space module processes local short-range features by receiving input from a one-dimensional convolutional layer, ensuring that these features can be selected or discarded before entering the SSM. We utilized local state space attention in place of the multi-head attention in the self-attention module, reducing the computational complexity of recursive reasoning from exponential to linear.

Secondly, to better integrate heterogeneous data features, we proposed a joint polyline encoding strategy. Its objective is to separate pedestrian agents from the dynamic agents and jointly encode them with traffic light information from the static scene (see Fig. 1). We observed that in uncertain motion prediction scenarios, the application of traffic regulations exerts a degree of implicit control over the potential movement states of agents. For example, pedestrian-priority traffic rules remain effective even in the absence of traffic lights, influencing vehicles and motorcycles alike. By jointly encoding pedestrians and traffic lights through a shared embedder, this jointly encoding strategy can independently interact with other dynamic agents to enhance the prediction accuracy of vehicle and motorcycle agents.

Lastly, we designed a prediction weight inference module. By redesigning selective state space with a cross-attention mechanism, we utilized independent query tensors to recursively infer multimodal candidate trajectories through interactions with the encoder and the keys and values from the previous recursive step. These candidate trajectories were then evaluated using a recurrent neural network to assign trajectory scores.

Our contributions are summarized as: (1) We propose the Tamba framework for motion prediction, which leverages the state space model to redesign computations of self-attention, resulting in computational complexity reducing significantly. (2) We propose a joint polyline encoding strategy. By integrating strongly correlated polyline types using independent or shared embedders, elements that impose similar behavioral patterns can better influence different agents, collectively contributing to the trajectory reasoning of these agents. (3) We redesign the Mamba decoder with cross-attention, allowing the joint scene encoding to share a unified scene representation, which further reduces the model's complexity. At the final stage, we introduced a prediction weight inference module to refine the predicted trajectories and enhance prediction accuracy. (4) Experimental results demonstrate that our method achieves state-of-the-art (SOTA) performance on Argoverse 1 and 2 datasets. Compared to advanced methods, our method reduces the number of parameters by 40%, achieves a four-fold increase in FLOPs. This represents a new level of balance between efficiency and performance in our model.

2. Related Works

2.1. State Space Model

Recently, the Mamba [6] framework has rekindled interest in state-space models (SSMs) [8, 10, 25] due to its introduction of an input-dependent selection mechanism, which enhances their applicability and performance. SSMs are renowned for their capacity to handle long-range dependencies and offer superior memory and computational efficiency compared to transformer-based architectures [28]. Hippo [7], a seminal contribution to SSMs, established the efficacy of these models in long-range sequence modeling tasks. Subsequent research, such as Vision mamba [39], has further refined the mechanisms underlying SSMs, resulting in substantial performance improvements. SSMs have demonstrated their versatility and robustness across a diverse set of domains, including computer vision, video analysis, medical imaging, graph-based learning, point cloud processing, and recommendation systems.

In the domain of trajectory prediction, recent studies have indicated that Motion Mamba [35] achieves notable success in predicting human trajectory time series. Building on these advancements, this work integrates the state-space mecha-

nisms of Mamba with attention mechanisms to address trajectory prediction tasks in dynamic traffic scenarios, thereby leveraging both the efficiency of SSMs and the adaptability of attention-based models.

2.2. Attention Trajectory Prediction Model

In the field of trajectory prediction, methods [11, 17] based on the attention mechanism have been widely adopted to enhance the model’s ability to capture and predict complex behaviors. These approaches leverage the capability of attention to focus selectively on important parts of the input, thereby capturing key temporal and spatial features that are crucial for predicting future trajectories.

Subsequently, several advanced approaches [15, 32] have utilized attention mechanisms for trajectory prediction specifically in multi-agent interaction environments, where understanding the interactions between different agents (such as vehicles, pedestrians, and other road users) is critical. These models employ social attention modules to focus on the movements and behaviors of surrounding vehicles, effectively improving the ability of the system to handle intricate interactive behaviors, which are a common aspect of real-world driving scenarios.

Moreover, attention mechanisms have also been successfully applied in models that integrate multimodal information [23, 24, 38]. These models dynamically weight and fuse different types of sensory inputs—such as image features from cameras and data from other sensors like LiDAR—through attention modules. This fusion process allows the model to better understand and represent complex traffic environments, effectively utilizing complementary data to enhance trajectory prediction performance.

3. Our Method

3.1. Overview

In the autonomous driving scenario, the input consists of the predicted dynamic agent, its surrounding agents, and the static scene context. Let the historical state of the i -th agent at time step t be represented as: $s_i^t = (p_i^t, \theta_i^t, t, v_i^t)$, where $p_i^t = (p_{i,x}^t, p_{i,y}^t)$ denotes the spatial position, θ_i^t represents the heading angle, t refers to the time step, and v_i^t denotes the velocity. The static scene context is represented by n polygons, which include elements such as lane boundaries, map edges, and sidewalks. The agent states s_i^t over T time steps within the observation window are used to predict K future trajectories over T' time steps.

In this paper, we propose the Tamba model to optimize the efficiency and accuracy of motion forecasting tasks. Our input includes s_i^t of dynamic and static agents, \mathcal{P} processed using a heterogeneous polyline encoding strategy to transform s_i^t into higher-dimensional features. We leverage three Tamba encoders to separately decompose (I) attentions in

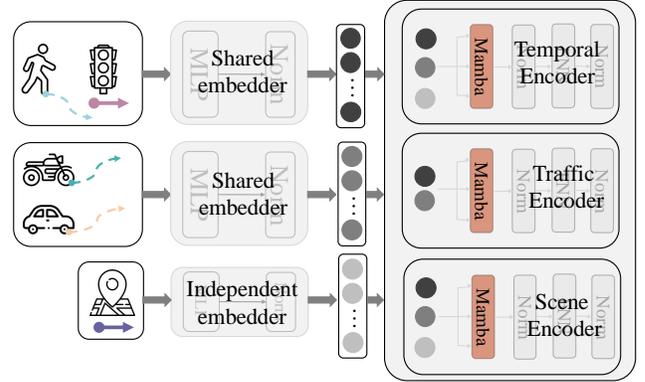

Figure 2. Overview of our Tamba encoder. We employ joint polyline encoding strategy to integrate strongly correlated polyline information and used three parallel encoders to interact with and associate these features. We applied a linear projection to map the attention output of Tamba back to the same dimensions as the input and used normalization to enhance the stability of the output.

each time step (t) over all elements, (II) attentions between all agents (A) and scene (S), and (III) attentions of traffic control elements (pedestrians and traffic lights) to other dynamic agents (motorcycles and cars). Then, concatenate features from encoders as output to a Tamba decoder, where we utilize cross-attention mechanism to generate proposal trajectories. Subsequently, we fused scene encoding with historical information to perform a secondary decoding of the proposal trajectories for refinement. Finally, the refined trajectories were optimized using a “winner-takes-all strategy” to obtain trajectory output.

Our model contains a novel heterogeneous polyline encoding strategy along with a decomposed feature fusion method for both static and dynamic agents. A redesigned Tamba encoder-decoder architecture. A refinement process to output the final predicted trajectory. In the following sections, we sequentially introduce the components in Tamba.

3.2. Joint Polyline Encoding

In multimodal traffic environment prediction tasks, different types of polylines possess unique geometric characteristics and semantic information. This study proposes a novel heterogeneous polyline embedding method to facilitate the fusion of dynamic and static context features, thereby providing a richer and more efficient feature representation. Specifically, we assign either independent or shared embedders to each type of polyline to effectively model various categories of information. Specifically, we jointly encode polylines with strong information associations, such as pedestrian trajectories and traffic light signals, using a shared embedder. This is because agents (pedestrians) and traffic lights typically impose similar behavioral patterns on other agents (vehicles) and often participate together in traffic control.

Thus, using a shared embedder reduces model complexity and promotes feature sharing, collectively influencing vehicle trajectory reasoning.

In contrast, independent embedders are used for polyline types with significant feature differences, such as lane lines and traffic signs in maps. Each embedder consists of a MLP layer and normalization layers to extract high-dimensional feature representations. The shared pedestrian and traffic light embedder uses a cross-category feature fusion layer to enhance the model’s sensitivity to different information sources. Polyline retain sequential information through positional encoding before being input to the embedders for feature extraction, followed by cross-category feature interaction via the Tamba encoder.

The mathematical representation of this process is as follows: Given the individual polyline data $P = \{p_1, p_2, \dots, p_n\}$, where $p_i \in \mathbb{R}^d$ represents a point on the polyline, n is the number of points, and d is the dimensionality, the embedding process is represented as: $\mathcal{P} = \text{Embed}(P)$. For the pedestrian and traffic light categories that share an embedder, the output feature representation $\mathcal{P}_{\text{joint}}$ is computed as follows:

$$\mathcal{P}_{\text{joint}} = \text{Fusion}(\text{Embed}(\mathcal{P}_{\text{pedestrian}}), \text{Embed}(\mathcal{P}_{\text{traffic}})), \quad (1)$$

where $\mathcal{P}_{\text{pedestrian}}$ and $\mathcal{P}_{\text{traffic}}$ are the input polylines for pedestrians and traffic lights, respectively, and Fusion represents the feature fusion operation.

3.3. Attention Tamba Encoder

In the proposed encoder, the input features \mathcal{P} are uniformly embedded through joint polyline encoding. The input feature shape of the Tamba encoder is (n, L, d) , where n denotes the number of encoded agents or scene elements, L represents the temporal sequence length, and d indicates the feature dimensionality at each time step.

Specifically, the sequence (L, d) undergoes linear transformations to generate the query, key, and value matrices, each with dimensions (L, d_k) , where d_k is the feature dimensionality used in the attention mechanism. The dot-product similarity between the query and key matrices is computed to yield an attention weight matrix of shape (L, L) , which captures the interdependencies between all time steps. Subsequently, these attention weights are employed to compute a weighted sum of the value matrix, yielding an output of shape (L, d_k) .

As the output feature dimensionality of the Tamba block (d_k) may differ from the input feature dimensionality (d), a linear projection is employed to align the attention mechanism’s output with the input dimensionality, resulting in (L, d) . This alignment ensures compatibility for the residual connection. Subsequently, the original input and the linearly projected attention output are combined via element-wise addition, yielding a resultant tensor of shape (L, d) .

To further stabilize the output, a normalization operation is applied, preserving the same dimensionality of (L, d) .

Subsequently, the features are processed by a feedforward neural network comprising two fully connected layers. The first layer projects the input to a higher-dimensional space d_{ff} , resulting in an output with dimensions (L, d_{ff}) . The second layer then maps the expanded features back to the original dimensionality d , restoring the shape to (L, d) . The output of the feedforward network is combined with the original input through a residual connection, preserving the output shape of (L, d) . A normalization operation is then applied to ensure stability, maintaining the final output shape of (L, d) for the entire encoder module. Thus, within the encoder module, the temporal sequence length (L) remains constant, whereas the feature dimensionality (d) may briefly change during processing but ultimately returns to its initial dimensionality.

Unlike traditional transformer models, Tamba adjusts the parameters of its state space model (SSM) based on the input data, allowing it to selectively retain or disregard different pieces of information within the sequence. Mathematically, Tamba uses a state space model to capture the temporal evolution of the input. Given an input sequence $\mathcal{P} = \{\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_T\}$, where T represents the sequence length and $\mathcal{P}_t \in \mathbb{R}^d$ is the input at each time step t , the SSM is governed by the following state evolution equation:

$$\mathbf{h}_{t+1} = A(\mathcal{P}_t)\mathbf{h}_t + B(\mathcal{P}_t)\mathbf{u}_t, \quad (2)$$

Here $\mathbf{h}_t \in \mathbb{R}^n$ represents the hidden state at the time step t , while $A(\mathcal{P}_t) \in \mathbb{R}^{n \times n}$ and $B(\mathcal{P}_t) \in \mathbb{R}^{n \times m}$ are matrices that depend on the input and evolve over time, and $\mathbf{u}_t \in \mathbb{R}^m$ represents the control input.

The output of the time step t is denoted as $\mathbf{y}_t \in \mathbb{R}^p$, and is computed as follows:

$$\mathbf{y}_t = C(\mathcal{P}_t)\mathbf{h}_t + D(\mathcal{P}_t)\mathbf{u}_t. \quad (3)$$

where $C(\mathcal{P}_t) \in \mathbb{R}^{p \times n}$ and $D(\mathcal{P}_t) \in \mathbb{R}^{p \times m}$ are also matrices that depend on the input. This formulation allows the system to dynamically adjust its parameters based on the current input, facilitating the selective retention and forgetting of information. The computational complexity of this method is linear, as the state update and output computation at each time step involve matrix-vector multiplication. The overall complexity is $O(T \cdot n^2)$, where T represents the sequence length and n is the state dimension.

Decomposed Attention Mechanism. We redesigned the self-attention computation, replacing the multi-head attention mechanism with state space model. After receiving the polyline encoding output \mathcal{P} , Tamba performs the attention decomposition using three parallel encoders. The detailed computation process is as follows:

(I) Spatiotemporal attention. The spatiotemporal attention for each agent A_i and scene elements (S) over the

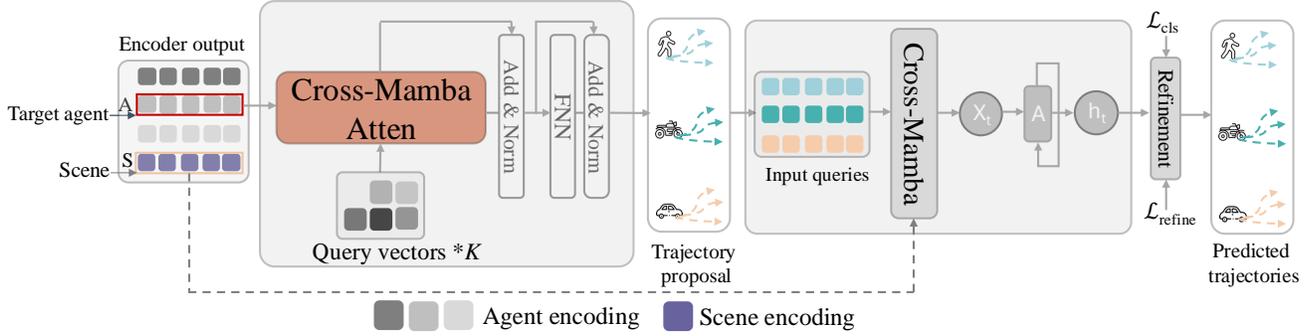

Figure 3. Overview of our Tamba decoding process. The outputs of the three Atten-Tamba encoders carry the context of both the static scene and dynamic agent states, which are concatenated and input into the Cross-Tamba decoder. For predicting the target agent’s trajectory, the decoder queries K trajectory modes using independent query tensors, while the encoder’s features combine the current state with recursive reasoning from the previous step, allowing all target agents to share a unified scene representation. During the secondary decoding, the predicted state of the proposed trajectory interacts once again with the current scene information, and a recurrent network assigns prediction weights to the proposed trajectories. The final output trajectory is obtained through refinement of these predictions.

\mathcal{P} at each time step t can be represented as: $Z_{\text{time}} = \text{softmax} \left(\frac{Q_t K_t^T}{\sqrt{d_k}} \right) V_t$, where $Q_t, K_t, V_t \in \mathbb{R}^{T \times d_k}$ are the query, key, and value matrices at time step t respectively, and d_k represents the dimensionality of the key vectors.

(II) Scene attention. For the attention between agent set A and scene elements S , let $A_i \in \mathbb{R}^{d_a}$ represent the embedding of agent i , and $S_j \in \mathbb{R}^{d_m}$ represents the embedding of scene element j . The attention calculation between agent i and scene element j is given by: $\alpha_{ij} = \frac{\exp(A_i^T S_j)}{\sum_k \exp(A_i^T S_k)}$, where α_{ij} denotes the attention weight, indicating the relevance of scene elements j to agent i . The output is a weighted sum of the scene elements features denote as:

$$Z_{\text{scene}} = \sum_j \alpha_{ij} S_j, \quad (4)$$

(III) Traffic Attention. Similar to Eq. 4, we use β_{ij} to represent the attention weight of traffic control elements (pedestrians and traffic lights) to other dynamic agents (e.g., motorcycles and cars). For a agent i , the output feature of traffic attention can be expressed as: $Z_{\text{traffic}} = \sum_j \beta_{ij} A_j$. This output is obtained by calculating the weighted sum of the embedded vectors A_j of all dynamic agents, where the weight β_{ij} reflects the impact of the traffic control elements on the dynamic agents. Through this interaction, the model can effectively focus on the influence of pedestrians on dynamic agent movement in non-traffic light scenarios.

3.4. Cross Tamba Decoder

The core challenge of trajectory decoding lies in addressing the ‘one-to-many’ problem, that is, how to generate K output results (possibilities) from one set of input features. In designing the decoder architecture, we drew inspiration from DETR’s approach [1] to solving the ‘one-to-many’ problem

in object detection tasks. Specifically, the number of K query vectors is initialized to represent different objects or candidate future trajectories. Through multiple iterations of the attention mechanism, each query vector extracts relevant information from the input features to produce K output results.

Crossed Dynamic and Static Attention. In the proposed cross-Tamba decoder, we designed it by using state space model to replace multi-head attention in the cross-attention mechanism. The query vector Q is separated to interact independently with the keys and values from the encoder’s output features. Specifically, the query vector is responsible for querying the modes of K trajectories, while K and V incorporate both the encoded features from the encoder and the reasoning from the previous recursive step. This design allows dynamic agents (e.g., vehicles and motorcycles) to better share mixed features (pedestrians and traffic lights), while all target agents share a single static scene representation and iteratively generate K different proposed trajectories over T' future recursive steps. During the training phase, the proposed trajectories are optimized using the MSE loss (L_{proposal}) based on the provided labels.

Trajectory Proposal. After proposing K predicted trajectories, we introduce a prediction weight inference module to compute the weight for each trajectory. In this process, we also use the Cross-Tamba module, which first fuses scene (S) with historical information to infer the likelihood of each predicted trajectory. Specifically, given each trajectory p_k (where $k = 1, 2, \dots, K$), we can represent it as:

$$p_k = \text{Cross-Tamba}(\text{Scene}, \text{Predictions}). \quad (5)$$

where Scene represents the feature representation of the current scene and Predictions contains all predicted proposal trajectories. At the head of the weight inference module, we

use a recurrent neural network (RNN) [22] to extract features from the final trajectories in order to generate a score for each trajectory. This RNN module can be represented as:

$$h_t = \text{RNN}(h_{t-1}, p_k), \quad (6)$$

where h_t is the hidden state at time step t , h_{t-1} is the previous state. Through this process, the RNN provides a mechanism for constraints across trajectories. When a trajectory conflicts with the environment or when there is an alternative trajectory that better fits the overall distribution, the RNN generates a prior confidence score for these trajectories. The confidence generated by the RNN can be represented as: $C_k = f(h_T)$, where C_k is the confidence score for trajectory p_k , h_T is the hidden state of the RNN at the final time step, and f is a nonlinear activation function.

This step ensures greater stability in the optimization process, such that the proposal trajectory considers not only the current prediction results but also the contextual environment and historical information, thereby enhancing the overall performance and robustness of the model.

Trajectory Refinement. We employed the same optimization approach as the baseline methods [37, 38] to perform mixture modeling of the predicted trajectories. The future trajectory of agent i is modeled as a mixture of Laplace distributions, as given by:

$$f(\{p_t^i\}_{t=1}^{T'}) = \sum_{k=1}^K \pi_{i,k} \prod_{t=1}^{T'} \text{Laplace}(p_t^i | \mu_{t,i,k}, b_{t,i,k}), \quad (7)$$

where $\{\pi_{i,k}\}_{k=1}^K$ are the mixing coefficients, representing the significance of each mixture component in the overall model. For each time step t , the Laplace density of the k^{th} mixture component is defined by the location parameter $\mu_{t,i,k}$ and the scale parameter $b_{t,i,k}$, which reflect the center and spread of that component. We use a classification loss L_{cls} to optimize the mixing coefficients in Eq. 7 by minimizing their negative log-likelihood. It is important to note that during this process, we stop the gradients of the location and scale parameters, focusing solely on the optimization of the mixing coefficients. This allows us to effectively focus on the classification task without affecting the trajectory's location and scale settings.

For optimizing the location and scale parameters, we adopt the ‘‘winner takes all’’ strategy [13], resulting in only the best-predicted trajectory from the proposal and refinement modules undergoing backpropagation. This approach ensures that the network is adjusted only based on the best predictions during training, thereby enhancing the accuracy and stability of the model. In addition, to prevent overfitting and improve model robustness, the refinement module halts the gradient propagation of the proposed trajectory. This strategy helps to effectively preserve the previously learned information during the adjustment of proposals.

Finally, our loss function integrates three components: the trajectory proposal loss (L_{proposal}), the trajectory refinement loss (L_{refine}), and the classification loss (L_{cls}), enabling an end-to-end training process. The expression is given as:

$$L_{\text{total}} = L_{\text{proposal}} + L_{\text{refine}} + \lambda L_{\text{cls}}. \quad (8)$$

4. Experiments

4.1. Datasets

Our experiments were conducted on the Argoverse 1 [2] and Argoverse 2 [12, 31] datasets. It contains extensive real-world autonomous driving scenarios and are designed to advance the development of autonomous driving technologies. The Argoverse 1 dataset includes 360-degree sensor data from the Pittsburgh and Miami regions in the United States, covering various road types and complex urban environments. Sampled at a rate of 10Hz, this dataset provides trajectory data of the ego vehicle over a 5-second time span, with 2 seconds of observation used to predict the path over the next 3 seconds, comprising over 30,000 such samples. Argoverse 2 further expands on the dataset by including richer sensor data, multimodal annotations, and extending the observation window. Specifically, it includes 11-second scenarios, with 5 seconds of observation followed by prediction of trajectories for the next 6 seconds. The dataset contains 250,000 scenarios and features a large object taxonomy comprising 10 non-overlapping classes, which is used for training and validating motion prediction models.

4.2. Metrics

We adopted evaluation methods consistent with prior research, using metrics such as $\text{minADE}_{(K)}$, $\text{minFDE}_{(K)}$, $\text{b-minFDE}_{(K)}$, and $\text{MR}_{(K)}$ to measure model performance in terms of error. Specifically, $\text{minADE}_{(K)}$ calculates the average L_2 distance between the ground truth and the most optimal trajectory among the K predicted trajectories across all future time steps, thereby assessing the overall prediction accuracy of the model over multiple time steps. $\text{minFDE}_{(K)}$ focuses on the prediction error at the final time step, measuring the model's ability to predict the final state accurately. $\text{b-minFDE}_{(K)}$ extends $\text{minFDE}_{(K)}$ by incorporating probability weighting, using $(1 - \hat{\pi})^2$ as a weight to account for prediction uncertainty, where $\hat{\pi}$ represents the probability score assigned by the model to the optimal predicted trajectory. $\text{MR}_{(K)}$ measures the proportion of the K predicted trajectories with an error greater than 2 meters, providing an assessment of the model's stability and the frequency of prediction failures. Together, these metrics offer a comprehensive evaluation of the model's prediction accuracy, stability, and uncertainty estimation. For the parameter K , we followed conventional values of 6 and 1. When the

number of predicted trajectories exceeds K , the top K trajectories with the highest probabilities are selected. In terms of lightweight evaluation, we used the number of parameters (M) and FLOPs(G) as the metrics.

4.3. Settings

We conducted all experiments under the same environment (batch size, epochs) using eight NVIDIA 3090TI cards with a batch size of 128. We used Adam for optimization, with an initial learning rate of 0.001. Training was conducted for a total of 50 epochs. We employed an adaptive learning rate adjustment strategy based on the validation set’s performance during training. Specifically, when the validation accuracy did not improve for five consecutive epochs, the learning rate was reduced to 0.1 times its original value.

4.4. Comparison with State of the Art

We compare our method with other state-of-the-art approaches across various evaluation metrics in Argoverse 2 dataset. As shown in table 1, our method demonstrates superior performance on key metrics such as minFDE₆ and minADE₆. Tamba achieves a b-minFDE₆ score of 1.79, compared to 1.91 for QCNet, 1.92 for BANet and 1.98 for

MTR. Additionally, Tamba achieves (MR₁) of 0.57, which is lower than that of other methods, such as QCNet (0.59) and MTR (0.58), indicating more stable prediction accuracy. Furthermore, Tamba has a parameter count of 4.54 M, which is significantly lower than QCNet (7.66 M), even compare to non-transformer models such as BANet (9.49M) and GANet (61.73M), Tamba achieving reductions of 52.0% and 92.7% respectively, while still outperforming both models. Additionally, Tamba achieves 27.3 GigaOps per second, which is 40% faster than QCNet’s 45.3 GigaOps per second. These results clearly demonstrate that Tamba is competitive in terms of accuracy but also excels in lightweight design and efficiency, providing an excellent solution for complex task.

On the Argoverse 1 dataset, our method outperforms other state-of-the-art (SOTA) methods across the board. On the leaderboard for the b-minFDE₆ metric, Tamba achieves a score of 1.67, while the second-best, QCNet, scores 1.69, and the third, BANet, scores 1.74. In terms of parameter count, our method requires 4.54M parameters, compared to 7.66M for QCNet, reflecting a 40% reduction. This further demonstrates the superiority of our approach in balancing efficiency and performance. For detailed performance met-

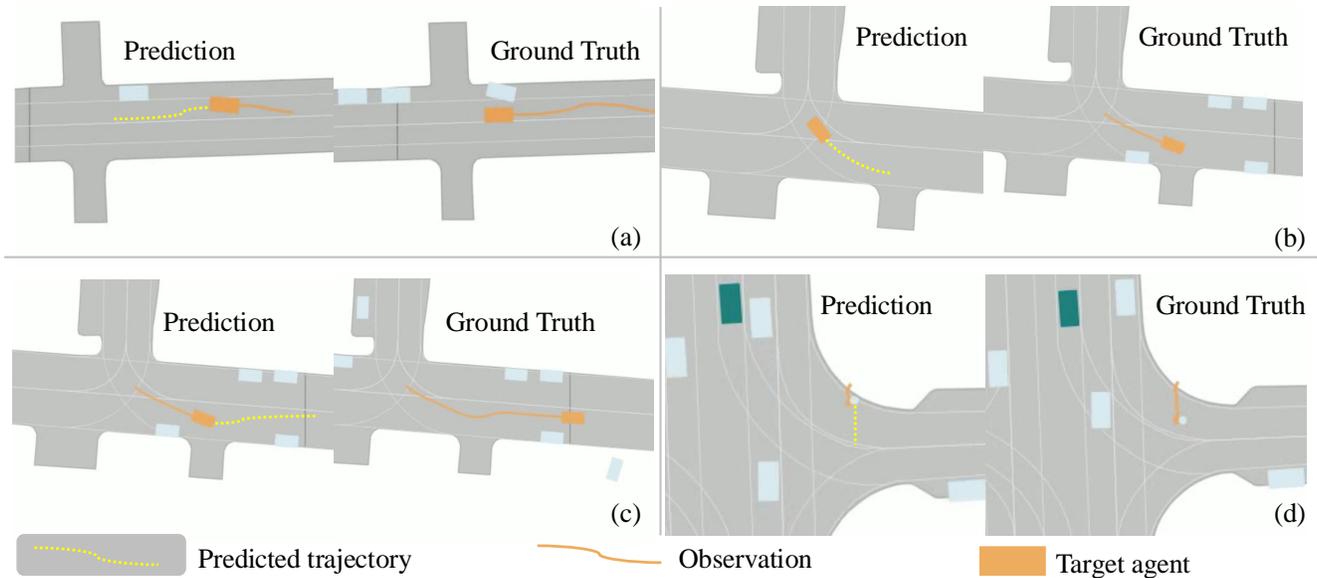

Figure 4. Qualitative results on the Argoverse 2 validation set. The target agent marked as orange with its surrounding agents marked as cold white. We conduct four different traffic scenarios. (a). Multi-agents in straight-road scenario, (b). Multiple agents on roundabout road, (c). Vehicle avoidance after roundabout, (d). Mixed scenario involving pedestrians and vehicles.

Method	w/ joint				w/o joint			
	minFDE ₆ ↓	minADE ₆ ↓	minFDE ₁ ↓	minADE ₁ ↓	minFDE ₆ ↓	minADE ₆ ↓	minFDE ₁ ↓	minADE ₁ ↓
Ours + Attention	1.094	0.763	3.037	1.376	1.093	0.728	3.035	1.372
Ours + Mamba	1.091	0.724	2.899	1.298	1.083	0.765	2.821	1.292
Ours + Tamba	0.951	0.673	2.742	1.265	0.955	0.680	2.745	1.272

Table 3. Ablation study on the components of the Tamba encoder-decoder. Experimental results are conducted on the Argoverse 2 [12, 31] validation set.

rics, please refer to table 2.

4.5. Quantization Results

We visualized the prediction results on the validation set. In some challenging sequences, the predictions made by the Tamba model are more reasonable and smoother compared to existing methods, effectively adhering to map constraints. In Figure 4, we present several multimodal prediction cases, the results demonstrate that the trajectories generated by Tamba are smoother and better adapted to complex road topologies, meeting the demands of vehicle navigation under diverse road conditions.

5. Ablation Study

We evaluated the effectiveness of the Tamba module. For comparison, we used both the traditional attention mechanism module and the Mamba module on the validation set. In addition, we assessed the efficacy of our proposed pedestrian-traffic light joint polyline encoding strategy. Table 3 presents the performance comparison of our proposed

three methods (including Attention variant, Mamba variant, and Tamba variant) under conditions with and without joint polyline encoding (w/ joint vs. w/o joint). Specifically, the table lists the performance of each method on two evaluation metrics: minFDE and minADE, considering both six predicted trajectories (minFDE₆ and minADE₆) and one predicted trajectory (minFDE₁ and minADE₁).

6. Conclusion

This paper introduces the Trajectory Mamba (Tamba) model, an efficient motion prediction model for the real-time and computational needs of autonomous driving. By employing a state space model (SSM) and a novel attention Tamba encoder-decoder, we reduce computational complexity and parameter count while maintaining state-of-the-art accuracy. Experiments on the Argoverse 1 and 2 datasets show that Tamba achieves superior inference speed and efficiency, with a fourfold reduction in FLOPs and over 40% fewer parameters compared to transformer-based models. These advantages make Tamba highly suitable for high-

dynamic environments requiring rapid responses.
