Abstract

Neuropsychiatric symptoms (NPS) are common features of neurodegenerative disease (NDD) but are relatively under-studied compared to cognition, especially regarding biomarkers. Further, emerging evidence describes the utility of systematic assessment of NPS across the cognitive continuum, even in advance of dementia. In this narrative review, we discuss the role of plasma biomarkers in relation to NPS across the cognitive continuum of unimpaired, subjective cognitive decline, mild cognitive impairment, and dementia. While Alzheimer's disease is the primary focus, vascular, Lewy body, and frontotemporal dementia etiologies are also discussed. Literature searches included NPS and dementia-related search terms with additional literature identified based on the author group's subject area expertise. We found that plasma biomarkers are a burgeoning field, and scalability and accessibility make them well-suited for the study of NPS across the disease continuum. In early-stage NDD, diagnostic biomarkers are best suited for discriminating NDD-related NPS from non-NDD psychiatric syndromes and/or NPS due to other causes. In those with dementia, monitoring and prognostic biomarkers may enable the assessment of treatment response or help predict the risk of worsening symptoms. We conclude that plasma amyloid- β and tau show great promise in assessing NPS, especially during early-stage disease, but inflammatory and genetic biomarkers may also play a role across the disease course. Systematic research is required, keeping in mind the ethical considerations of knowing biomarker status in early-stage disease.

Introduction

Disease-specific biomarkers may assist in patient diagnosis, improving accuracy over clinical assessment alone, and accelerating therapeutic delivery.¹ Mechanistic biomarkers can inform understanding of disease, and are important for diagnostics and therapeutics.² However, even autopsy-based classification criteria are based on the quantity of pathology for a given age in the presence of dementia and only at a specific point in time³; thus, the traditional sense of "gold standard" may not apply.⁴ For Alzheimer's disease (AD), the most common cause of neurodegenerative disease (NDD), some frameworks define AD on the basis of pathology alone, whether or not clinical symptoms are present. In contrast, other frameworks define AD based on both pathology and clinical symptoms.^{5,6} Notably, both AD pathology and cognitive impairment become very common after the age of 85 years.^{7,8} Similarly, efforts are underway to incorporate biomarkers to redefine Lewy body diseases, especially in early stages,⁹ and in vascular cognitive impairment.^{10,11} Frontotemporal dementias are also under investigation, but disease heterogeneity provides challenges in identifying specific but broadly applicable biomarkers.¹²

In AD, complicating the diagnostic issue is dynamic change of biofluid amyloid- β (A β) biomarkers throughout the disease course. Amyloid pathology accumulates in the brain for 10–15 years while individuals remain clinically unimpaired, but high amyloid levels are associated with a higher risk of developing cognitive impairment.^{13,14} Cerebrospinal fluid (CSF) A β_{42} declines even before amyloid plaques are apparent on brain imaging,¹⁵ and a low A $\beta_{42/40}$ ratio may reflect soluble protofibrils more closely than amyloid plaques.¹⁶ Fluid biomarkers, including tau, phosphorylated at positions 181, 217, and 205 (p-tau₁₈₁, p-tau₂₁₇, and p-tau₂₀₅, respectively), change later than A $\beta_{42/40}$ in the course of the disease and are more strongly associated with cognitive symptoms.^{17–20} A CSF peptide, including the microtubule-binding region of tau (MTBR-tau₂₄₃), changes even later in the course of AD and has the highest associations with tau and cognitive symptoms demonstrated thus far by a fluid biomarker.²¹ But how do neuropsychiatric symptoms (NPS) or behavior fit into this time course?

Incorporating NPS into this biological understanding of the initiation and early stages of AD may increase complexity but may also reveal the physiological basis of behavioral change in AD.²² Behavioral variants have not been

systematically evaluated in association with mechanistic biomarkers. Biomarkers can unlock critical insights in pathogenesis in addition to diagnosis. The complexity of change in biomarkers with dementia onset supports a pivotal and integrated biological role for A β , neurodegeneration, oxidative damage, and mitochondria in the transition to AD.^{23,24}

The purpose of assessing biomarkers in patients with dementia is to focus on marking treatment response or assessing risk of worsening symptoms so that intervention strategies can be developed, i.e., monitoring, prognostic, and predictive biomarkers.²⁵ Here, it is unlikely that AD diagnostic biomarkers will be useful. In particular, A β accumulation can plateau as cognitive impairment worsens, meaning that sensitivity in detecting NPS prevalent in late-stage neurodegeneration may be lost, and p-tau₂₀₅ or MTBR-tau₂₄₃ may be better markers at later stages.^{2,18,21} Biomarkers of dementia progression may provide a way to assess the risk for emergent NPS, since most NPS seem to correlate with a more severe disease course. However, whether these NPS reflect direct mechanisms (i.e., treatment targets) remains at equipoise. Thus, earlier in the disease course (i.e., preclinical and prodromal disease), susceptibility/risk and diagnostic biomarkers may be more appropriate to explore links with NPS to help distinguish between NDD-related NPS and NPS due to other etiologies.²⁵ However, examining the relationship between NPS and underlying neuropathology is challenged by variability in the profile and measurement of specific types of NPS^{26,27} and biomarkers, including changes over the course of the disease,²⁸ and the age of onset,²⁹ type,³⁰ severity,³¹ and regional distribution³² of the underlying neuropathology.

In this narrative review, we explore associations between NPS and NDD biomarkers across the cognitive spectrum, from cognitively unimpaired (CU) to subjective cognitive decline (SCD), mild cognitive impairment (MCI), and dementia. The primary focus is AD, for which there are the most data, attendant with the high prevalence of AD relative to other dementias.

Basics of plasma biomarkers

The extent to which any specific analyte measured in blood correlates with its concentration in CSF or brain tissue is highly variable. It depends on multiple processes, including the structure and function of the blood-brain barrier and the rates of synthesis and clearance of analytes in the periphery and the brain.^{20,33} Although many processes involved in steady-state equilibria across tissue compartments have been elucidated, much less is known regarding the extent to which a substance formed in the brain reaches the blood in its original form, particularly given the potential impact of anthropometric, demographic, and genetic features on biofluid levels of any substance.³⁴ Preclinical

studies of blood biomarkers can be informative, but they are not consistent across species. Thus, how well blood biomarker concentrations reflect brain concentrations, and the impact of peripheral production and clearance rates, is not fully understood. The accepted technique for determining the amounts and rates of brain contribution to the blood in humans is to label the central pool of an analyte by administering a heavy isotope-labeled precursor of the analyte of interest.³⁵

Initial studies of A β peptides in CSF and blood have demonstrated significant between- and within-immunoassay variation over time. This assay “noise” was greater in blood than in the CSF matrix, obscuring the relationship between plasma A β and brain amyloid plaques as detected by higher precision assays.³⁶

A major challenge in measuring blood-based AD biomarkers is that the concentrations of A β and tau are substantially lower in the blood than in CSF. For example, concentrations of plasma A β ₄₂³⁷ and tau³⁸ are approximately 30 and 2–5 times lower, respectively, than in CSF. Another challenge is that plasma and serum contain higher total protein concentrations, which can interfere with the measurement of AD blood biomarkers. As a result, the development of blood biomarkers was slowed due to the high sensitivity required, the limited correlation between blood and CSF biomarkers, and the high variability encountered when using conventional enzyme-linked immunosorbent assays or other immunoassays.^{39,40}

Technological advances in the last decade have contributed to the development of more accurate assay platforms capable of sensitively measuring A β peptides, p-tau proteins, and neurodegeneration biomarkers (neurofilament light chain [NfL] and glial fibrillary acidic protein [GFAP]) in the blood. These platforms include, among others, the Single Molecule Array (Simoa) immunoassay, immunoprecipitation mass spectrometry (IP-MS), Meso Scale Discovery platform, Elecsys immunoassay, and immunomagnetic reduction. An overview of available assays and platforms is available elsewhere.²⁰ A head-to-head comparison of eight assays assessing the performance of plasma A β _{42/40} for detecting abnormal brain amyloid, as measured by positron emission tomography (PET) and CSF, suggested that IP-MS assays performed better than many of the immunoassays in both cognitively impaired and unimpaired older adults.^{41,42} More recent studies have found that some immunoassays have performance similar to IP-MS assays in some cohorts, supporting that immunoassays may be adequate for certain applications.^{43,44}

Head-to-head comparisons of plasma p-tau biomarkers have also suggested that IP-MS assays perform slightly better than immunoassays for predicting A β pathology and that p-tau₂₁₇ predicts brain amyloid pathology more strongly than p-tau₁₈₁ or p-tau₂₃₁.^{44–48} However, compared to immunoassays, IP-MS may require more specialized

equipment and larger sample volumes, making implementation at the population level more challenging. A recent advancement is the development of Nucleic Acid Linked Immuno-Sandwich Assay (NULISA), which is a multiplex assay allowing testing of 120 NDD-related proteins to attomolar-level sensitivity using small sample volumes.^{49–51} NULISA has demonstrated discriminative accuracy for abnormal amyloid-PET (area under the receiver operator curve (AUC = 0.918)) and tau-PET (AUC = 0.939),⁵² comparable to Simoa,⁵³ and potentially easier to implement at the population level than IP-MS. Further research on scalability is required.

Comorbid conditions affecting the interpretation of AD blood-based biomarkers

AD blood biomarker levels are more susceptible to change due to peripheral factors than their PET and CSF counterparts. Due to physiological mechanisms, these peripheral factors can alter the interpretation of blood-based levels and potentially result in false positive or false negative diagnoses.⁵⁴ Here, we highlight three factors that warrant consideration: chronic kidney disease (CKD), obesity, and cardiac conditions.

Multiple studies have shown that a diagnosis of CKD, low estimated glomerular filtration rate, and high creatinine are associated with higher blood levels of all A β peptides, p-tau, NfL, and GFAP.^{55–58} Reduced renal clearance of these proteins has been proposed as the underlying mechanism. Thus, CKD could lead to a false positive diagnosis if a blood p-tau marker is used and a false negative diagnosis if blood A β is used. One potential strategy to mitigate the effects of CKD on blood biomarkers is to utilize ratio-based measures. For example, CKD has not been associated with as pronounced a change in blood A $\beta_{42/40}$ or p-tau₂₁₇/tau ratios.^{56,57,59,60}

Obesity has been associated with lower levels of the aforementioned AD blood biomarkers,^{55–57,61} but not with their CSF counterparts.^{61,62} One explanation is that individuals with obesity have larger blood volumes, resulting in lower concentrations of blood AD biomarkers. Similar to CKD, ratio-based measures may mitigate these effects.^{46,56,57,60}

Evidence also suggests associations between blood A β levels and cardiac conditions. A β can accumulate in the hearts of patients with AD, contributing to AD-related cardiac amyloidosis.^{63,64} Further, plasma A β_{40} accumulation in vascular walls and heart tissue has been associated with cardiac dysfunction, coronary heart disease, heart failure, and cardiovascular disease mortality.⁶⁵ Higher plasma A β_{42} levels have been associated with a higher risk of heart failure.⁶⁶ Entresto[®] (combination of sacubitril and valsartan), a drug used for heart failure, has been shown to reduce plasma A $\beta_{42/40}$ but not CSF A $\beta_{42/40}$.⁶⁷ As a result, it remains unclear how best to utilize plasma A β measures

for screening or diagnosis of AD among individuals with heart conditions. A β_{40} can also accumulate in cortical and leptomeningeal vessel walls, as is the case in cerebral amyloid angiopathy (CAA), a progressive cerebral small vessel disease that contributes to morbidity and mortality from hemorrhagic stroke and vascular dementia.⁶⁸

Standardization and pre-analytic variables

Several sources of variation and pre-analytical factors should be considered when interpreting AD blood-based biomarkers. These factors range from circadian rhythms, dietary influences, and other person-specific variables to the collection and processing of the blood samples.⁶⁹ Pre-analytical factors that may affect levels of blood A β , p-tau, total tau, NfL, or GFAP include the collection tube type (e.g., anticoagulant used), time to centrifugation and storage, and storage temperature (Table 1).⁷⁰ Other sources of variability include protein instability following multiple freeze-thaw cycles and the distinct sensitivities of antibodies used in different assays.^{69,71–74} A β_{42} is sensitive to pre-analytical factors, but even more so is total tau,^{70,73} for which details such as time to centrifugation and centrifugation temperature are essential variables.⁷⁰ Certain factors may mitigate some of this variability, including fully automated technologies, ultrasensitive approaches, multiplexing, and rigorous standards such as those required in Clinical Laboratory Improvement Amendments (CLIA)-certified labs.^{69,75} Wider adoption of standardized pre-analytic protocols across global centers is recommended to ensure consistency, improve the reproducibility of tests, and minimize variability of results.⁷⁰

Neuropsychiatric symptoms overview

Evaluating biomarker levels in relation to NPS requires an accurate definition of what constitute NPS. Most definitions agree that NPS must emerge in the context of an underlying neurological disease, affect function beyond what can be attributed solely to the disease, and persist for a minimum time frame at a specified severity level.^{77–79} In addition, other potential causes (e.g., delirium or psychiatric conditions unrelated to NDD) must be excluded as the primary cause of NPS, although “delirium-like” NPS have been defined as a possible prodrome of dementia with Lewy bodies (DLB).⁸⁰

Mild behavioral impairment

Over time, the definition of NPS in dementia has become more nuanced due to several advancements in the field. First, there is growing recognition that NPS may emerge in advance of dementia, and sometimes even in advance of cognitive decline, as opposed to being limited to moderate to severe dementia. For example, the construct of mild

Table 1. Effects of preanalytical factors on plasma AD biomarkers.

Tube Matrix for plasma (anticoagulant): EDTA, heparin, fluoride, or citrate, and Serum	Lithium-heparin versus EDTA	Higher plasma A β ₄₀ and A β ₄₂ , lower total tau (Roche-Elecys) ⁷³
	Na-citrate versus EDTA	Higher plasma A β ₄₀ and A β ₄₂ levels (various assays)* ⁷⁰ Higher plasma A β ₄₂ , A β _{42/40} ratio, total tau, p-tau ₁₈₁ , GFAP, and NfL; no significant differences in A β ₄₀ Lower total tau, p-tau ₁₈₁ , A β , NfL, GFAP ⁷⁰ Lower plasma A β ₄₀ , A β ₄₂ , and total tau, Higher A β _{42/40} ratio (Roche-Elecys) ⁷³ Lower plasma A β ₄₀ and A β ₄₂ levels using various assays* ⁷⁰ Lower plasma NfL, GFAP, and higher A β ₄₂ and A β _{42/40} ratio; no significant differences in A β ₄₀ , tau, or p-tau ₁₈₁ ⁷¹
Tube parameters	Heparin, citrate, fluoride, or serum versus EDTA	Lower plasma A β levels (INNO-BIA) ⁷²
	Aprotinin addition	No effect on plasma A β levels (INNO-BIA) ⁷²
Aliquot volume Collection	Serum	Variable (no effect, higher or lower) compared to plasma EDTA ⁷⁰
	Material: PP, PET	No effect on plasma A β (INNO-BIA), or plasma A β ₄₂ or A β ₄₀ by various assays*
Centrifugation temperature and force	Sample volume (mL): 2.7, 4.9, 8.5, 9, 10	No effect ⁷³
	EDTA cation: K2, K3	No effect ⁷³ No effect on plasma A β (INNO-BIA) ⁷²
Whole blood stability in EDTA tube	Gel separator: +/-	No effect ⁷³
	Tube filling: 1/2 or full	No effect on any markers ⁷³ Decrease of total tau in one study
Aliquot volume Collection	250, 500, 1000 μ L	No effect on plasma A β ₄₂ and A β ₄₀ by various assays* ⁷⁰
	Needle size, location of blood draw, tube collection order	No effect ⁷⁰
Centrifugation temperature and force	Centrifugation temperature	Plasma A β ₄₂ slightly higher when centrifuged at 20°C compared to 2–8°C (INNO-BIA) ⁷²
	Force	Plasma A β ₄₀ levels slightly lower when centrifuged at 20°C compared to 2–8°C (INNO-BIA) ⁷² No effect on plasma A β ₄₂ and A β ₄₀ (various assays)* ⁷⁰ Lower total tau levels with centrifugation at 4° ⁷³ Centrifugation at \geq 2000 g favored for optimal recovery of A β ₄₀ (INNO-BIA) ⁷²
Whole blood stability in EDTA tube	Time to centrifugation (h): 0.5, 1, 2, 6, 24	Plasma A β ₄₀ and A β ₄₂ stable up to 1 h; plasma A β _{42/40} ratio stable up to 2 h; total tau stable up to 6 h (Roche-Elecys) ⁷³
	Time to centrifugation (h): 1, 4, 24, 72	Plasma A β ₄₂ and A β ₄₀ stable up to 4 h at 20°C and up to 24 h at 2–8°C (INNO-BIA) ⁷²
Whole blood stability in EDTA tube	Time to storage	Whole blood A β ₄₂ and A β ₄₀ stable up to 24 h at 4°C but not at RT* and decrease afterwards; effects <u>not</u> mitigated by A β _{42/40} ratio for most assays* ⁷⁰ Plasma GFAP, NfL, and p-tau ₁₈₁ levels stable if tubes held >24 h at RT or 4° ⁷⁰
		Lower whole blood total tau if held at RT for 3–24 h, and higher if held at 4°C for 3–24 h before centrifugation ⁷⁰
Whole blood stability in EDTA tube		No effect of delay in fresh plasma storage up to 6 h on A β ₄₂ , A β ₄₀ , or total tau levels 4°C (Roche-Elecys) ⁷³
		Lower plasma total tau if tubes held 3–24 h at RT or 4°C for 3–24 h ⁷⁰
Whole blood stability in EDTA tube		Plasma A β ₄₂ and A β ₄₀ stable up to 24 h at 4°C (but not at RT) and decrease afterwards; effects can be mitigated by use of A β _{42/40} ratio in most assays* ⁷⁰
		Short term storage at <24 h had no effect on any markers except for total tau which decreased if stored for \geq 2 weeks at 4°C ⁷⁰

(continued)

Table 1. Continued

EDTA plasma storage after thawing	+4°C; time to measurement (h): 0, 1, 6, 24	Fresh EDTA plasma storage +4°C; time to measurement (h): (0, 1, 3, 6, 24) stable up to 6 h (Roche-Elecys) ⁷³
RT; time to measurement (h): 0, 1, 6, 24	A β ₄₂ and A β ₄₀ decreased after intermittent \leq 2-week storage at 4°C before -80°C ⁷⁰	
Number of tube transfers	\leq 5	No effect of intermittent \leq 2-week storage at -20°C (before -80°C) for any markers ⁷⁰
Effect of the collection tube on stability during freezing	Material (PP, PET) Sample size (mL): 2.7, 4.9, 8.5, 9, 10	A β ₄₂ and A β ₄₀ stable up to 6 h at +4°C and 1 h at RT (Roche-Elecys) ⁷³
Freeze/thaw cycles (from -80°C)	EDTA cation (K2, K3) Gel separator (+/-) \leq 4 cycles	A β _{42/40} ratio stable up to 24 h (both +4°C and RT) (Roche-Elecys) ⁷³
Freeze/thaw cycles (-25°C)		No effect ⁷³
Circadian rhythm		No effect ^{70,73}
		No effect ⁷³
		No effect on serum NfL, plasma A β ₄₂ , total tau levels by Simoa ⁷⁴
		Minor reductions in plasma A β ₄₀ (Simoa) at cycle 3 with further reductions with \geq 4 cycles ⁷⁴
		No effect on plasma A β ₄₂ and A β ₄₀ levels (various assays)*, p-tau ₁₈₁ , tau, or NfL ⁷⁰
		GFAP levels increased after \geq 4 cycles ⁷⁰
		Decrease in plasma p-tau ₁₈₁ at \geq 4 cycles, decrease in plasma EDTA A β ₄₀ at \geq 4 cycles can be mitigated by A β _{42/40} ratio ⁷¹
		Serum NfL and GFAP stable up to 4 cycles, serum A β ₄₂ and A β ₄₀ and total tau reduced after 2 cycles ⁷¹
		No effect on A β ₄₂ , A β ₄₀ , tau, or p-tau ₁₈₁ ⁷³
		Small effect on A β ₄₂ , A β ₄₀ and tau, no effect on A β _{42/40} ratio (Roche-Elecys) ⁷³
		No diurnal variation in plasma A β levels (INNO-BIA) ⁷²

*Various assays including Precivity-AD (C2N Diagnostics) which is immunoprecipitation liquid mass spectrometry, a MALD-TOF-MS method using a protocol modified from Nakamura et al.,⁷⁶ Euroimmun ELISA, Aracion ELISA, Simoa 4-PLEX E, and Simoa 3-PLEX A.

OA β : A β oligomerization tendency assay

behavioral impairment (MBI)⁷⁹ stipulates that NPS may occur well before clinical dementia during the preclinical or prodromal disease phases. MBI symptoms comprise the domains of decreased drive and motivation (apathy), emotional dysregulation (mood/anxiety), impulse dyscontrol (impulsivity, agitation, abnormal salience), social inappropriateness (impaired social behavior), and abnormal perception or thought content (psychosis). Early in the disease process, however, MBI can present as a variable or subtle mix of symptoms from several domains. Thus, assessing the global construct of MBI may offer advantages for early detection and prognostication over individual domains.^{81,82}

Syndromic criteria for NPS in neurodegenerative diseases

Another advancement in NPS research pertains to the development or refinement of syndromic diagnostic criteria for NDD-related behavioral changes (i.e., apathy, psychosis, agitation) as opposed to simple consideration of individual

symptoms with variable measurement approaches. For example, apathy criteria developed by Alzheimer's Association International Society to Advance Alzheimer's Research and Treatment (ISTAART) and International Society for CNS Clinical Trials Methodology working groups, using a modified Delphi process and expert consensus, specify: 1) the presence of NDD; 2) symptom presence for a minimum of four weeks; 3) a change from the individual's baseline; 4) symptoms in two of the following dimensions: diminished initiative, interest, and emotional expression/responsiveness; and 5) exclusion of other confounding factors.⁸³ Similarly, revised criteria for AD-related psychosis developed by an expert panel led by the International Psychogeriatric Association (IPA),⁸⁴ and the research framework developed by ISTAART⁸⁵ emphasize that: (1) symptoms may emerge in MCI (for IPA criteria) or even in SCD or CU stages (for ISTAART criteria); (2) symptoms must be present for a minimum of four weeks; (3) overlap with agitation and affective symptoms must be noted (IPA) or are exclusionary if psychotic symptoms are better accounted for by an affective or

agitation syndrome (ISTAART); (4) symptoms may be fluctuating or persistent; (5) symptoms must affect function; and (6) other etiological categories must be excluded. The syndromic criteria for agitation, developed by an IPA working group, specify: (1) the existence of dementia or a pre-dementia syndrome (i.e., MCI); (2) behaviors in one or more of verbal aggression, physical aggression, and excessive motor activity domains that are associated with distress and impaired function; and (3) not attributable solely to another medical or psychiatric etiology.⁷⁸

While revisions to existing criteria have helped clarify distinct phenotypic NPS presentations in the context of NDD, other behaviors that overlap with primary psychiatric disorders, such as hoarding, obsessive-compulsive disorder, disinhibition, impulsiveness, and affective dysregulation, remain understudied. A key question remaining in the characterization of NPS is the extent to which these symptoms can be differentiated from pre-existing or primary psychiatric pathology, currently better determined by symptom natural history. This critical area needs biomarkers, particularly minimally invasive biofluid markers that can be readily translated to various clinical and research settings. Ultimately, these biomarkers would help distinguish primary psychiatric symptoms from NPS related to NDD and also determine if there are comorbid primary psychiatric–NDD etiologies. Depression, for example, may reflect recurrent early-onset depression, late-life depression, or late-onset depression as a manifestation of NDD, with few cross-sectional clinical features clearly distinguishing one from the other. Similarly, late-life schizophrenia may be hard to distinguish from NDD-related psychosis, although symptom phenomenology might help distinguish the underpinning pathology.⁸⁶ For example, the presence of complex delusions and auditory hallucinations would more strongly indicate late-life schizophrenia, whereas visual hallucinations and misidentification delusions may suggest prodromal DLB, and delusions of theft are the most common psychotic symptom in AD.^{8487–89} However, the identification and utilization of biofluid biomarkers could be fundamental for differentiation when psychosis phenomenology is not so distinct and symptoms related to both clinical entities coexist.

An important issue concerning NPS is the extent to which symptoms may overlap, co-occur, or fluctuate between assessments. Factor analyses suggest that symptoms can be subdivided into separate subgroups, such as depression, agitation, psychosis, and elation.⁹⁰ While it is generally acknowledged that certain symptoms may co-exist with each other, few biomarker studies to date have addressed this issue by focusing on subtypes or by controlling for the presence of specific NPS when examining individual symptoms.

Most biomarker studies published to date examining correlates of NPS have relied on established scales such as the Neuropsychiatric Inventory (NPI).^{91,92} The NPI quantifies NPS across 12 domains: delusions, hallucinations, agitation/aggression, dysphoria, anxiety, euphoria, apathy,

disinhibition, irritability/lability, aberrant motor activity, night-time behavioral disturbances, and appetite/eating abnormalities. Severity scores for each domain are rated 1 to 3, where 1 is the lowest severity and 3 is the highest. An additional score out of 5 is given to rate caregiver burden, with 1 being the lowest and 5 being the highest. Most research has used the NPI, which has demonstrated excellent utility. In the ADMET 2 clinical trial of methylphenidate for apathy, for example, a score of ≥ 4 to identify clinically significant apathy corresponded well with apathy diagnostic criteria.⁹³ Other scales used in biomarker studies, particularly those in preclinical and prodromal samples of older adults, include symptom-specific assessments focused on traditional psychiatric phenomenology (e.g., Patient Health Questionnaire-9,⁹⁴ Geriatric Depression Scale,⁹⁵ Beck Anxiety Inventory⁹⁶).

More recently, NPS in patients with preclinical or prodromal NDD, predominantly AD but also Parkinson's disease/Lewy body diseases, have been assessed using the Mild Behavioral Impairment Checklist (MBI-C), which evaluates the presence and severity of five MBI symptom domains, consistent with ISTAART MBI diagnostic criteria: decreased motivation, emotional dysregulation, impulse dyscontrol, social inappropriateness, and abnormal perception or thought content.^{81,97} The MBI-C specifies that these NPS must be later-life emergent, persist for at least six months, and represent a change from the person's baseline. Although the MBI-C was initially developed for the assessment of MBI in older adult populations without dementia, it is still a valid tool to assess NPS in older adults living with dementia.⁹⁸ When the MBI-C is not available, for instance, in legacy datasets, MBI can still be operationalized and studied in relation to blood biomarkers using the NPI and its derivatives.⁹⁹

Importance of specifying cognitive status when reporting neuropsychiatric symptoms

NPS are prevalent across the spectrum of neurocognitive disorders, from CU through MCI and all stages of dementia.^{100,101} While the range of NPS is broadly similar, comprising changes in apathy, mood/affect, agitation, disinhibition, and psychosis, the rationale underlying the search for biomarker correlates will likely differ depending on the cognitive status. Studies exploring the association between NPS and cognition using a nomothetic approach have generally shown that the presence of NPS is either consistent or increases as cognition worsens and disease progresses.¹⁰² Consistently, several studies have found greater NPS frequency with worse cognitive status and/or progression across the AD continuum (i.e., controls, SCD, MCI, dementia).^{103,104} Meta-analytic evidence further supports significant associations between NPS and cognition,

as well as a greater presence of NPS in patients with dementia who have poorer cognitive performance.¹⁰⁵

Additionally, studies have suggested that NPS, particularly those meeting MBI criteria, in participants with MCI are associated with both a higher rate of progression to dementia^{99,106} and a lower probability of reversion to CU,¹⁰⁷ regardless of the presence of A β pathology.¹⁰⁸ In addition to the potential mediating role of cognition in the association between biomarkers and NPS,¹⁰⁹ other factors, such as sex, cognitive complaints, worries, ethnicity, and apolipoprotein E gene (*APOE*) haplotypes, seem to modulate the strength of the association between NPS and AD biomarkers or incident dementia.^{103,110-114}

While evidence has strongly linked MBI to elevated dementia risk,^{99,11,21,15-120} there remains a degree of uncertainty as to whether later-life emergent NPS are sequelae of underlying NDD or psychiatric risk factors for cognitive decline and dementia.^{115,121} Notably, the hazard of incident dementia associated with MBI differs based on cognitive status. For example, when comparing MBI-psychosis to no NPS, the hazard ratio (HR) for incident dementia was 9.96 in CU and 3.38 in MCI.¹²² While MBI-psychosis was more frequent in MCI, with a higher absolute progression rate to dementia than in CU, these findings suggest that the earlier MBI emerges, the more significant its relative contribution to risk. Similar findings have been reported for MBI domains of decreased motivation and emotional dysregulation.^{111,112} Thus, while incorporating natural history and cognitive status is helpful in classifying NPS, biomarkers can help further differentiate NPS due to NDD, normal aging, or other psychiatric conditions in both clinical and research settings, especially in CU and SCD populations. Molecular differences, general and sex-specific, may contribute to the heterogeneity of NPS in different neuropsychiatric conditions, potential targets for multiomic approaches aiming at the development of precision medicine strategies.¹²³ In this respect, biomarkers for behavior are analogous to biomarkers for cognition, namely, to differentiate normal cognitive aging from pathological changes due to underlying NDD, which can be challenging in otherwise healthy individuals.¹²⁴

Data and results so far on studies of neuropsychiatric symptoms and plasma biomarkers across the cognitive continuum

Biomarkers specific to NPS may differ from biomarkers of NDD, as previously demonstrated in CSF.¹²⁵ NPS may arise due to myriad possible etiologies, influenced in part by the nosology and nomenclature applied in detection and measurement. NPS biomarkers may guide symptom-specific treatment and can be used in conjunction with disease biomarkers to identify the underlying etiology. Presently,

much more work is needed to understand when and how to differentiate late-life NPS due to various possible etiologies, but the application of AD blood biomarkers is a logical starting point. Here, we summarize data published so far on the association between NPS and plasma biomarkers. Recognizing the importance of specifying cognitive status when discussing NPS, we stratify findings based on cognitive group (i.e., CU, SCD, MCI, dementia) where possible, acknowledging that some studies were also conducted in mixed samples with various cognitive statuses.

Cognitively unimpaired adults

Several studies have reported significant cross-sectional and longitudinal associations between A β pathology and at least some NPS in CU participants. A review of these studies has been published elsewhere.²⁸ Cross-sectional, positive associations were found between A β deposition and anxiety and MBI-C total scores in CU participants.^{126,127} Longitudinal evidence has shown that: (1) depressive¹²⁸ and anxious¹²⁹ symptoms in participants without objective cognitive impairment successfully predicted cognitive decline, particularly in the presence of A β deposition; and (2) A β pathology at baseline was significantly associated with longitudinal increases in depression and anxiety symptomatology in CU participants.¹³⁰⁻¹³²

The association between tau burden and NPS has been less studied, and the results are less conclusive. The bulk of the evidence arises from established biomarker approaches, and major evidence in favor of significant associations comes from longitudinal studies of CU participants at baseline rather than cross-sectional designs.²⁸ One study reported positive correlations between baseline CSF total tau and p-tau₁₈₁ levels and longitudinal increases in NPI-Q scores and mood/affective symptoms.¹³⁰ Another study observed significant associations between neuritic plaques and psychotic symptoms (but not NPI-Q total scores).¹³³ A recent longitudinal study of 286 CU older adults at baseline found that NPS using the NPI-Q were independently associated with greater progression to MCI over an eight-year period (while adjusting for CSF and PET biomarkers).¹³⁴ For MBI, in a large sample of CU participants, global MBI status was found to predict clinically diagnosed and neuropathologically confirmed AD.¹¹⁹ This finding was later replicated in a cohort consisting of both CU and MCI participants.¹²⁰ Psychosis, while low frequency, had the strongest effect of all MBI domains. Another large study of CU and SCD participants found that in reference to a no NPS group, CU participants with MBI had a 2.76-fold greater incidence of dementia and SCD participants with MBI had a 1.99-fold greater incidence of dementia. For conventionally measured NPS not meeting MBI criteria, incidence rates did not differ from the no NPS group. Of MBI progressors to dementia, 76% developed AD.¹³⁵

A small study that included CSF biomarkers provides biological insights into NPS in preclinical AD. In

A β -positive participants who were CU with or without SCD, NPS measures (i.e., MBI-C) were associated with early-stage AD Braak region tau-PET tracer binding and higher CSF p-tau₁₈₁ levels, while cognitive performance measures (i.e., ADAS-DR) were not linked to tau.¹³⁶

Dementia-free older individuals (mixed CU, SCD, and MCI)

Several studies have explored the association between NPS and blood-based biomarkers in mixed samples that include CU, SCD, and MCI, sometimes denoted “dementia-free”. In a 5-year study of 331 dementia-free older adults (47 with MCI), higher plasma A β ₄₂ levels at baseline predicted incident late-onset depression.¹³⁷ In another 6-year study of 223 dementia-free individuals, those with depression and lower A β _{42/40} at baseline were at greater risk of incident AD compared to those with non-A β depression.¹³⁸ Of those with A β -associated depression, *APOE* e4 carriers were at greater risk of AD than non-carriers.

Some studies also investigated associations between blood-based non-core AD biomarkers and individual NPS, mainly depression. One study used targeted proteomics in ADNI to explore links with depressive symptoms. Here, hepatocyte growth factor, insulin polypeptides, pregnancy-associated plasma protein-A, and vascular endothelial growth factor were found to be related to depression.¹³⁹ Other than depression, one cross-sectional aging study found that lower vitamin B₆ levels were associated with anxiety.¹⁴⁰ These studies exploring the relationship between blood analytes, using various assays with unknown levels of precision to NPS symptoms, and with limited or no replication to date serve to highlight the wide range of possibilities to be explored in future research.

The MBI construct has been particularly useful for better understanding the relationship between NPS and core AD plasma biomarkers amongst dementia-free older adults, highlighting the importance of incorporating natural history into NPS assessment. To date, several longitudinal studies have been published on this topic. MBI was shown to be associated with higher plasma p-tau₁₈₁ levels over 4 years, an association not seen in participants with NPS that did not meet MBI criteria (i.e., non-MBI NPS).¹⁴¹ In addition to a decline in memory and executive function, survival analyses demonstrated a 3.92-fold greater dementia incidence in MBI participants, with no significant differences between the non-MBI NPS and no NPS groups. Recently, a secondary analysis of data from a nutritional supplement randomized controlled trial was reported, in which both MBI and plasma p-tau₁₈₁ were measured.¹⁴² In this sample of dementia-free older persons (60% MCI), MBI-psychosis was associated with an increase in plasma p-tau₁₈₁ over one year. Further, a tau-PET study demonstrated effect modification by amyloid status for MBI-associated tau tracer uptake in early-stage AD Braak

regions; the association was observed only in A β -positive participants.¹⁴³ These findings extend those from the BioFINDER-2 preclinical-AD study,¹³⁶ and highlight a need to investigate the relationship between MBI and plasma tau in the context of A β . Most recently, in a study of 101 dementia-free older adults, those with MBI had higher plasma p-tau₂₁₇ levels and higher odds of p-tau₂₁₇ positivity than participants without MBI.¹⁴⁴ These findings support the growing evidence base linking MBI with AD proteinopathies, and the utility of MBI status for disease detection in advance of dementia.

Aside from studies focusing solely on plasma tau biomarkers, a cross-sectional study of 139 dementia-free participants (53 with MCI) reported an association between lower plasma A β _{42/40} and greater MBI burden. Among MBI domains of affective dysregulation, decreased motivation, and impulse dyscontrol, only affective dysregulation was significantly associated with lower plasma A β _{42/40}.¹⁴⁵ In a longitudinal study of 583 dementia-free older adults (330 with MCI), MBI was associated with a greater increase in plasma NfL levels.¹⁴⁶ Although not in plasma, it should be noted that MBI participants exhibited CSF p-tau₁₈₁, p-tau₁₈₁/A β ₄₂ ratio, and tau/A β ₄₂ ratio trajectories consistent with NDD across two independent cohorts with MCI; in one cohort, MBI was also related to A β ₄₂ and A β _{42/40} changes over 4 years. In contrast, these same biomarkers did not differ between participants with non-MBI NPS and no NPS, except for a longitudinal association with total tau in one cohort. Importantly, of MBI progressors to dementia, 81% developed AD.¹⁴⁷

There have been some studies investigating the association between other plasma analytes and NPS in non-dementia samples. One study has shown that the presence of inflammatory cytokine interleukin-(IL)-1 β correlates with agitation severity.¹⁴⁸ Higher plasma levels of IL-6 were also associated with a higher prevalence of depression in a cohort of 69 CU or MCI individuals.¹⁴⁹ Monocyte chemoattractant protein-1 (MCP-1) was associated with future risk of depression.¹⁵⁰ One cross-sectional aging study found that lower vitamin B₆ levels were associated with anxiety.¹⁴⁰

Mixed samples including dementia

Comparatively few studies have combined participants with and without dementia into one study cohort. One cross-sectional study of 1005 older adults (118 with MCI or dementia) found an association between plasma p-tau₁₈₁ and p-tau₂₁₇ and greater agitation and disinhibition.¹⁵¹ A study in a memory clinic cohort including CU older participants and patients with MCI and mild dementia found no association of plasma p-tau₁₈₁, GFAP, and NfL with overall NPS cross-sectionally, but GFAP and NfL were associated with greater NPI-Q scores over time.¹⁵² Applying an untargeted proteomics approach in the same

cohort revealed that a combination of 15 plasma proteins, including C-reactive-protein (CRP), complement factor H, alpha-1 microglobulin, noelin, and apolipoprotein H, predicted current and future NPS,¹⁵³ which was further validated in the ADNI cohort.¹⁵⁴ Finally, a study of patients from outpatient memory clinics found a correlation between brain-derived neurotrophic factor (BDNF) levels and aggressiveness.¹⁵⁵

A multiplex biochemical biomarker study of 146 known plasma analytes from the Alzheimer's Disease Neuroimaging Initiative (ADNI) found several analytes that were highly associated with depressive symptoms, including hepatocyte growth factor, insulin polypeptides, pregnancy-associated plasma protein-A, and vascular endothelial growth factor.¹³⁹ Medications, body mass index, *APOE* alleles, serum glucose, and CSF A β levels were also assessed and did not significantly affect the associations between these plasma marker levels and depressive symptom scores. Future studies in this area could conduct subgroup analyses examining the levels of these plasma analytes comparing MCI, probable AD groups, and CU individuals.

A few studies have also explored the associations of NPS with plasma inflammatory biomarkers in samples with mixed cognitive statuses. A memory clinic cohort found that NPS were associated with a panel of serum inflammatory markers, including IL-6, eotaxin-3, and CRP.¹⁵⁶ In a small sample of 27 individuals with mild AD or amnestic MCI, those with more apathy symptoms had higher serum levels of soluble tumor necrosis factor (TNF) receptors.¹⁵⁷ Nevertheless, it should be taken into account that these blood-based inflammatory markers are poor and non-specific biomarkers of clinical findings in general.¹⁵⁸ Given the range of analytes studied and assays used, much work remains to be done to establish which, if any, non-core AD biomarkers reliably predict emergence of specific NPS symptoms.

AD dementia

AD, the most common type of dementia, is very frequently accompanied by NPS, including apathy, motor disturbances, depression, anxiety, agitation and, less commonly, delusions, hallucinations, and disinhibition.²⁶ Owing to its high prevalence, a large amount of research has been conducted on NPS in AD dementia relative to preclinical or prodromal stages of NDD. The wealth of research in this area has enabled a more precise understanding of individual NPS in relation to plasma biomarkers, as summarized below.

Agitation. In recent years, agitation in patients with AD has been associated with several blood-based biomarkers. As observed in non-dementia samples, high levels of IL-6, cortisol, and greater natural killer cell activity, all indicating pro-inflammatory conditions, were associated with agitation severity.¹⁵⁹ However, there is conflicting evidence

regarding the relationship between IL-6 and agitation, with one study finding no association in their sample.¹⁶⁰ Baseline TNF levels¹⁶⁰ and 4-hydroxynonenal¹⁶¹ have been both observed to be associated with agitation severity and oxidative stress.

In AD carriers of the *APOE* e4 allele, plasma A β _{42/40} has been associated with longitudinal increases in agitation.¹⁶² Elevated levels of irisin have been reported in patients with agitation and were positively correlated with the duration of agitated symptoms.¹⁶³ While BDNF was associated with agitation in a mixed cognition cohort, as previously mentioned,¹⁵⁵ this association did not hold in samples comprising only AD dementia participants.¹⁶³ In females, the *APOE* e4 allele confers the greatest risk of agitation severity compared to other allele combinations.¹⁶⁴ While there have been various primary investigations assessing the relationships between blood biomarkers and agitation severity, many of the studies have not yet been replicated and sometimes report conflicting results.

Apathy. Apathy has been observed in some cohorts to be the most prevalent NPS in AD, with a point prevalence of 49%.¹⁶⁵ Positive correlations between apathy and plasma levels of γ -aminobutyric acid (GABA), a key inhibitory neurotransmitter in the central nervous system, have been observed.¹⁶⁶ The presence of apathy has also been associated with a higher plasma/platelet clusterin ratio in AD.¹⁶⁷ However, evidence for the association between plasma homocysteine levels and apathy has been mixed. In one study, plasma homocysteine levels were associated with total Apathy Evaluation Scale (AES) scores in a sex-dependent manner: females with apathy had significantly higher homocysteine levels than those without. After controlling for cognition, depression, and vascular risk factors, plasma homocysteine was correlated with the cognitive and behavioral subdomains of AES, but not with the emotional domain.¹⁶⁸ In contrast, another group found no significant difference in mean plasma homocysteine levels between patients with AD who had NPS and those who did not.¹⁶⁹ One explanation for this discrepancy could be the way NPS were operationalized as well as possible differences in assays; in the second study, apathy was included within an 'affective cluster' alongside anxiety, depression, and irritability, potentially obscuring distinct associations with apathy specifically.¹⁶⁹

Depression. In studies examining depression, positive correlations were found between plasma GABA levels and depression scores on the NPI.¹⁶⁶ Another study reported differing plasma homocysteine levels in patients in the moderate AD stage with or without depression; plasma homocysteine levels were higher in patients with major depression compared to those without major depression.¹⁷⁰ Moreover, patients with moderate AD also exhibited more severe behavioral disturbance symptoms on the Cornell Scale for Depression in Dementia than patients with mild

AD, suggesting a potential relationship between elevated homocysteine levels, more burdensome behavioral disturbances associated with major depression, and dementia progression.

Dementia stage-specific associations between plasma ceramide levels and NPS were also observed in another study of patients with mild and moderate-to-severe AD; specifically, plasma ceramide levels were positively associated with NPI-depression only in those with moderate-to-severe AD.¹⁷¹ However, another study reported elevated plasma ceramide levels in patients with recent major depression (within two years) compared to patients with past or no history of major depression, regardless of dementia status.¹⁷² A major limitation of this latter finding was the small sample size and the combination of CU individuals with patients with AD, as no significant differences in mean ceramide levels were found between these two groups.

One study examined plasma cortisol concentration and depressive symptoms.¹⁷³ Although mean plasma cortisol was higher in AD compared to controls, it was only slightly higher in patients with AD who had depression than in those who did not have depression. This study concluded that plasma cortisol levels were more reflective of cognitive impairment than the severity of depression in this population.

Psychosis. Several blood-based biomarkers have been assessed for their relationship with the severity of psychosis among patients with AD. Homocysteine serum levels were positively correlated with psychotic symptom severity,¹⁷⁴ whereas IL-7, IL-15, and IL-18 were all negatively correlated with psychosis severity.¹⁷⁵ When stratified by *APOE* e4 carrier status, IL-15 was the best predictor of total NPS (including psychosis) in carriers, while IL-18 and TNF were the best predictors among non-carriers.¹⁷⁶ Many of these biomarker assessments are standalone investigations that require replication to improve the evidence supporting the utility of these biomarkers for patient risk assessments and treatment response observations in the context of psychosis.

Less common NPS in AD. Plasma/platelet clusterin ratio has been observed to be associated with greater severity in NPI domains of disinhibition, aberrant motor behavior, and irritability in patients with AD.¹⁶⁷ Another group found positive associations between plasma ceramides and delusions in the mild AD stage.¹⁷¹ Other NPS, such as hallucinations, elation, anxiety, and appetite changes, are less frequent and did not have positive findings in other studies. Many of the studies focusing on less frequent NPS reported associations with CSF biomarkers, not plasma, and hence were not included in this review.

NPS in AD genetic association studies. Analysis of plasma samples has facilitated the study of genetic factors and their role in developing NPS in AD, sometimes implicating certain pathogenic pathways or specific neurotransmitter

systems. The e4 allele of the *APOE* gene is widely recognized as the most substantial genetic risk factor for sporadic late-onset AD.¹⁷⁷ A genome-wide association study identified a significant association between the *APOE* e4 allele and psychosis in AD.¹⁷⁸ However, a review paper on *APOE* haplotypes and NPS in AD revealed inconsistent findings: some studies found significant associations between the *APOE* e4 allele and more agitation/aggression, hallucinations, delusions, and late-life depression or anxiety, while other studies failed to find any association.¹⁷⁹ A systematic review and meta-analysis of 53 studies found no association between *APOE* e4 alleles and depression, anxiety, apathy, agitation, irritability, or sleep disturbances in MCI or AD.¹⁸⁰ However, it has been proposed that *APOE* e4 alleles may differentially exert their effects on behavioral symptoms in AD depending on the cognitive stage¹⁸¹ or may act as modulators of the effects of other genes on such behavioral manifestations,¹⁸² particularly in earlier dementia stages.¹⁸³ Recent studies on sex-specific associations found that *APOE* e4/e4 females showed increased NPS burden and higher NPS severity scores than *APOE* e3/e3 females, with no such association in males.¹⁶⁴ A 1-year longitudinal study of 793 patients with AD found that participants with the *APOE* e4 allele exhibited symptoms of irritability/lability, delusions, hallucinations, and agitation/aggression.¹⁸⁴

The remaining studies reviewed here are candidate gene association studies which are prone to false positives so the findings should be interpreted with caution. Dopamine function is mediated by five distinct receptor subtypes (DRD1, DRD2, DRD3, DRD4, and DRD5).¹⁸⁵ Studies have been conducted to examine the associations of NPS among patients with AD with dopamine receptor polymorphisms. One study found that psychosis and aggression were significantly more prevalent in *DRD1* B2/B2 homozygotes, while psychosis alone was more prevalent in *DRD3* B1/B1 or B2/B2 homozygotes.¹⁸⁶ Neither aggression nor psychosis were associated with variants of the *DRD2* or *DRD4* genes.¹⁸⁶ Similarly, another study found associations between *DRD1* variants and psychosis and aggressive behavior, as well as an association between a *DRD3* polymorphism and psychosis, but not with aggression in AD.¹⁸⁷ Specifically, carriers of the *DRD1* B2 allele displayed more frequent symptoms of aggression and hallucinations, and individuals homozygous for the *DRD3* B1 allele were more likely to experience delusions. These findings contrasted with those of a previous study where homozygosity for either *DRD3* allele was associated with psychosis in AD.¹⁸⁶ Another study, however, did not confirm these associations between *DRD3* polymorphisms and psychotic symptoms (delusions and hallucinations) on the NPI.¹⁸⁸ A longitudinal study of 395 patients with probable AD found associations between *DRD3* and elation, and between *DRD4* with agitation/aggression and *DRD4* with depression; however, these findings did not remain significant after

correction for multiple testing.¹⁸⁹ *DRD1* and *DRD2* were not associated with these symptoms, and no significant associations were found between *DRD1-4* variants and the other NPS of delusions, hallucinations, psychosis, and aberrant motor behavior. To conclude, larger studies and longitudinal data are required to better understand the relationship between *DRD1-4* variants and NPS.

Serotonergic function is modulated by the serotonin transporter (SERT), which is responsible for the reuptake of 5-hydroxytryptamine (5-HT) at the synapse. SERT is an important target for the pharmacological management of psychiatric symptoms. Two variants that influence the transcription rate of the *SERT* gene are the linked polymorphic region (LPR) variant and the variable number tandem repeat (VNTR) variant. One study found the 102 T polymorphism of the 5-HT2A receptor to be significantly associated with delusions and agitation/aggression in 96 patients with AD,¹⁹⁰ consistent with other studies.¹⁹¹ However, one study showed no associations between LPR and symptoms of depression, psychosis, anxiety, or agitation.¹⁹² A longitudinal study of 367 patients with AD found a significant relationship between the LPR variant long allele and NPI-irritability scores, and between the VNTR variant 10-repeat allele and NPI-psychosis scores. No associations between these variants were found with depression, anxiety, or agitation/aggression.¹⁹² To conclude, SERT could play a role in the development of symptoms of irritability or psychosis, where these findings could be replicated further in larger cohorts. Associations with anxiety and depressive symptoms could also be further studied in relation to the *SERT* gene.

Various genetic markers have been implicated in psychotic symptoms. The rs2153674 single nucleotide polymorphism of the G72 locus, implicated in other psychotic disorders, was significantly correlated with the severity of delusional aspects of AD-induced psychosis.¹⁹³ In a single nucleotide polymorphism investigation, the T allele of rs6494223 of the *CHRNA7* gene (the gene for the alpha 7 nicotinic acetylcholine receptor) was associated with a higher severity of delusions, with cognition being controlled for using the Mini-Mental State Examination.¹⁹⁴

Vascular cognitive impairment and dementia

Vascular cognitive impairment and dementia (VCID) refers to cognitive decline in which cerebrovascular disease either causes or contributes to the cognitive syndrome.¹⁹⁵ Diverse pathophysiological mechanisms may underlie VCID, including cerebral small vessel disease, ischemic stroke, macro- and micro-hemorrhages, and CAA.¹⁹⁶ Traditionally, neuroimaging has been central to the identification of cerebrovascular pathology and the pathophysiological processes that lead to VCID.

Compared to core AD biomarkers, blood-based biomarkers for VCID are less established. CAA is one potential cause of VCID, leading to both small vessel disease (e.g.,

lacunar infarctions, periventricular hyperintensities, cerebral microhemorrhages) and macrohemorrhages. CAA has been associated with lower A β ₄₀ measured in the CSF.¹⁹⁷ However, only lower A β ₄₂ in the hereditary Dutch-type CAA was found to be significant, while no differences were observed between sporadic CAA and control groups for A β ₃₈, A β ₄₀, or A β ₄₂.¹⁹⁸ Emerging blood-based biomarkers for VCID due to subcortical small vessel disease include inflammatory cytokines, markers of oxidative stress, and endothelial-derived adhesion proteins (e.g., soluble intracellular adhesion molecule-1 and soluble vascular cell adhesion molecule-1).^{199,200}

Depression is the best-studied NPS in VCID, and literature on 'vascular depression' may be sufficiently salient to inform future work on blood-based biomarkers of NPS in VCID.²⁰¹ While not studied specifically in those with VCID, older adults with depression have been found to have a greater burden of white matter hyperintensities on neuroimaging as well as higher levels of IL-1 β and TNF receptor-2, and lower levels of glial-derived neurotrophic factor, adiponectin, and serum brain-derived neurotrophic factor.²⁰¹ The recent identification of brain endothelial injury markers, such as vascular-endothelial cadherin, and their association with AD pathology and cognitive outcomes in preclinical AD, offers opportunities to further explore associations of their plasma levels with NPS in AD.²⁰²

Frontotemporal dementia

FTD encompasses a class of NDDs characterized by progressive neuronal loss in the frontal and temporal lobes, with a typical onset in middle age.²⁰³ While there is heterogeneity in clinical presentation, FTD is most often characterized by language and communication impairments (e.g., primary progressive aphasia [PPA]) and/or abnormal behavior.²⁰⁴ Behavioral variant FTD (bvFTD) is typified by disinhibition, personality changes, and a decline in socially accepted behavior, judgment, and self-control. These often co-occur with other NPS, of which the patient is typically unaware. The relationship between plasma biomarkers and NPS in FTD is an area of active research.

NfL, a measure of neuro-axonal damage, has been a prime candidate for discriminating FTD from AD in both CSF and plasma studies, with comparable findings.²⁰⁵ NfL has also demonstrated high discriminatory power (area under the receiver operating characteristic curve of 0.84 to 0.96) to differentiate bvFTD from primary psychiatric disorders (e.g., major depressive disorder, schizophrenia, conversion disorder).^{206,207} Recent work has found that plasma GFAP, a measure of astrogliosis, was elevated in patients with FTD (n = 72) compared to those with AD (n = 56); there were no group differences in NfL.²⁰⁸ Plasma GFAP was also associated with progression to moderate FTD. Additionally, plasma GFAP was significantly higher in patients with

FTD with symptomatic *GRN* pathogenic variants compared to *C9orf72* expansion carriers or patients with *MAPT* pathogenic variants.²⁰⁹ Finally, plasma tau concentrations were found to be higher in bvFTD (n = 71) and PPA (n = 83) compared to healthy controls (n = 22), as well as in patients with *MAPT* pathogenic variants compared to those with *C9orf72* expansions or *GRN* pathogenic variants.²¹⁰

FTD can be challenging to diagnose, especially at its early stages, as its NPS often overlap with symptoms due to other etiologies. Given this overlap, most biofluid studies of NPS in FTD examine differentiating dementia etiologies and time to cognitive impairment.¹² Biomarkers help to understand the biological underpinnings of these symptoms. The levels of certain biomarkers might be associated with the degree of neuroinflammation or neuronal loss in specific brain regions, which in turn could relate to the severity of NPS in dementia.

Dementia with Lewy bodies

DLB is the second most common neurodegenerative type of dementia in older people, resulting from the aggregation of α -synuclein.²¹¹ Core features of DLB include visual hallucinations and REM sleep behavior disorder (RBD), though other behavioral symptoms, including depression, apathy, anxiety, hallucinations in other sensory modalities, and delusions, may also occur.^{212,213} Together, these symptoms often cause greater behavioral burden than in other dementia syndromes.^{214,215} Proposed biomarkers for DLB encompass various modalities such as single-photon emission computed tomography (SPECT), magnetic resonance imaging (MRI), polysomnography, CSF analysis, PET, and skin biopsies.²¹³ While there are many tools available to help assist with the detection of the various biomarkers and symptoms associated with DLB, there is very little research to date on plasma biomarkers that could be utilized to detect DLB or the behavioral symptoms that may accompany Lewy body diseases. A study on the association between NPS and neuropathological correlates suggests that LB and AD pathology contribute differently to NPS, likely through an additive process.²¹⁶ However, studies involving biomarkers to confirm these findings are still lacking. The few studies that have investigated plasma biomarkers in the context of DLB have done so in relation to cognitive performance and isolated RBD,^{217,218} or have mixed samples including older adults with other NDDs.²¹⁹ The dearth of research investigating the relationship between these symptoms and pathological changes highlights the critical need for more research in this field.

Ethical aspects of biomarker research in neuropsychiatric syndromes

AD biomarker testing may be performed by research studies, clinical trials, or as part of a clinical evaluation.²²⁰⁻²²² In all

settings, individuals should be offered a choice of whether or not to learn their results,²²³⁻²²⁵ a practice that supports commitment to patient-centered care, transparency, and informed patient choice. Effective communication and support during the process of sharing biomarker information with patients is important because learning about risk can be distressing. Studies demonstrate that patients do experience distress regarding the return of biomarker results.²²⁶ Individuals watching amyloid PET disclosure videos experience declines in positive feelings and increases in negative feelings.²²⁷ Best practices for disclosure to promote autonomy and well-being include pre-test counseling and post-test explanations, guidance, and support, including therapeutic alternatives and information on healthy life choices.²²⁸ A comprehensive example is the Biomarker Disclosure Toolkit.²²⁹

With the advent of the U.S. Food and Drug Administration-approved AD-specific treatments, it is important to promptly identify potential candidates for treatment (i.e., patients with a clinical diagnosis of early symptomatic AD with biomarker confirmation of A β pathology). While there are many reasons why clinicians may not provide a clear diagnosis,²³⁰⁻²³⁵ these delays increase the risk of NPS, which typically worsen as dementia progresses and complicate collaborative decision-making. Patients may be less likely to recognize their symptoms due to anosognosia.²³⁶ NPS, such as apathy, anhedonia, impulsivity, and delusions, can exacerbate existing issues with the ability of patients to protect vital self-interests such as financial security.²³⁷ Delays thus disempower patient choice, especially since certain treatments are likely to be most effective early in the disease.²³⁸

The field of AD biomarkers is rapidly evolving, and the appropriate use of biomarkers depends on clinicians being knowledgeable about recent developments. For example, with their greater accessibility compared to CSF testing or imaging techniques, blood-based biomarkers may expand access to AD biomarkers in socioeconomically disadvantaged societies, including low- and middle-income countries.²³⁹ However, most AD biomarker studies have been performed in cohorts lacking racial and ethnic diversity that are healthier, have higher education levels, and have higher incomes than the general population.^{240,241} This is especially concerning because biomarker values appear to be associated with factors such as race, medical conditions, and greater contextual factors that encapsulate structural and social determinants of health.^{55,242-244} Although using different cut-offs for different groups has been proposed, it is vital to avoid adjusting for group differences in a manner that perpetuates disparities.²⁴⁵ For example, it would be preferable to use biomarker measures that perform consistently across groups or to adjust for factors (e.g., renal clearance) that may underlie group differences.²⁴⁶

In conclusion, rapid progress in biomarker development is providing opportunities to improve AD diagnosis, but using these advances to benefit patients requires an

understanding of the limitations of these tests. Further, it is essential to consider if, when, and how to communicate these potentially life-changing results.

Clinical implementation

This narrative review has shown that many variables need consideration when assessing associations between plasma biomarkers and NPS. Heterogeneity in NPS definitions and case ascertainment, heterogeneity in cognitive status or syndrome, and heterogeneity in biomarker assays and platforms all contribute to heterogeneity in findings. Further, different approaches are required depending on the purpose of the biomarker—diagnostic biomarkers may differ from prognostic or monitoring biomarkers. Clarity of purpose will be essential for clinical implementation.

The AD Core 1 biomarkers ($A\beta$, p-tau) are likely the first to be used in the assessment of NPS in clinic, following their use for assessment of cognitive impairment. However, clinicians will first need to be comfortable using the biomarkers for NPS, which will likely occur after experience and comfort with the use of these biomarkers for cognition.

This manuscript serves as a reference and starting point by identifying strengths and opportunities in the field. Some clinical implications may be derived from the available evidence based on contexts of use.²⁴⁷

- Plasma biomarkers will hardly replace standardized neuropsychiatric assessments for diagnosis of NPS. Nonetheless, they could be useful to select specific cohorts for clinical trials based on the expected outcomes.
- Plasma biomarkers could be potentially useful to forecast behavioral decline, and for prognostic predictions particularly concerning responses to specific therapeutic interventions. Once validated for target engagement, they can also be used to monitor therapeutic response and assess efficacy.
- Finally, plasma biomarkers could be used to detect adverse reactions or safety concerns of a behavioral therapy. In the general population, they might potentially be used to detect the behavioral effects of exposure to environmental agents. All these implications will depend upon well-grounded research aiming to investigate associations of plasma biomarkers with meaningful behavioral outcomes.

Limitations and directions for future research

This review aimed to summarize evidence on a topic that has not yet been widely or systematically studied. As this area of study is quite nascent, and the literature scant, we conducted a narrative review rather than a systematic review. We leveraged

the subject matter expertise of the author group and collective knowledge of the field to guide us. The authors implemented NPS and dementia-relevant search terms, supplemented by a review of reference lists, and their own knowledge of the field. We tried to include all relevant articles that were available. Nevertheless, the lack of a systematic review methodology should be considered a limitation of this work. In addition, the assessed studies had different inclusion and exclusion criteria, used different protocols to assess NPS and plasma biomarkers, combined patients at different dementia stages, and had diverse sample sizes (often small), thus making it challenging to reach more comprehensive conclusions.

Most of the included studies were cross-sectional, a result of the fact that this topic has not received the required attention from large, multi-center studies. In addition, the scientific community has provided much more attention to AD in comparison to other dementia syndromes, resulting in a discrepant proportion of articles related to AD specifically. Future research should address the relevance of plasma biomarkers in longitudinal studies of NPS, and consider the etiological diversity of dementia.

Standardization of pre-analytical protocols must be widely adopted to harmonize methods and ensure the reliability of research results.²⁴⁸ Variability in the associations of plasma biomarkers with neuropathology is still widespread due to the non-adoption of proper control of pre-analytical factors that may interfere with biomarker measurements. Additionally, the summarized studies of non-core AD biomarkers should be viewed as suggestive at this point due to use of non-standardized assays. Additional research, especially longitudinal studies are required.

Plasma p-tau species are non-invasive and reliable indicators of both amyloid and tau pathology and more accurate than plasma amyloid biomarkers to predict conversion to dementia.²⁴⁹ However, their negative predictive value is still not high enough. Different plasma analytes are differentially informative of brain events at various stages of AD. Much still needs to be learned about the processes that control both the production and clearance of analytes when dealing with a biofluid biomarker that affects the interpretation of steady-state concentrations. The field requires a broader variety of plasma biomarkers that are both sensitive and specific to neuropathology.^{20,250} Relatedly, the science continues to evolve. For example, CSF $A\beta$ relationships with other biomarkers of AD-related processes, such as those for oxidative damage, are complex, nonlinear, and not fully understood.^{251–254} Similarly, in *PSEN1* variant carriers and in patients with DLB, a pleiotropic change is suggested at the time of cognitive failure.^{255,256} Future studies need to incorporate behavior into this type of modeling.

Finally, implementing widely available diagnostic criteria for NPS and differentiation from pre-existing psychiatric pathology is essential for proper associations with plasma biomarkers. Standardizing neuropsychiatric assessments for detecting NPS consistently may improve their detection and differential

Table 2. Actionable items.

Research Goals	Harmonization of protocols for neuropsychiatric assessment and biomarker studies (and particularly considering pre-analytical factors that may interfere with such assessments) is essential to reach more comprehensive conclusions. Biomarker studies that assess associations with neuropsychiatric syndromes must consider potential sex differences and be conducted in cohorts with racial and ethnic diversity, as well as diverse educational and income levels. Longitudinal studies with large cohorts that aim to investigate associations between neuropsychiatric syndromes and plasma biomarkers throughout the Alzheimer's disease continuum while considering the presence of mild behavioral impairment may help elucidate cause-and-effect relationships. Systematic reviews assessing associations of plasma biomarkers with neuropsychiatric syndromes will be needed when more studies on the field are available.
Clinical Goals	The associations of some less studied plasma biomarkers with behavior should also be the target of future studies. Standardization of neuropsychiatric assessments may improve the detection of neuropsychiatric syndromes and differential diagnoses with primary psychiatric syndromes, thus reducing costs and benefitting patients, caregivers, and healthcare systems. A broader variety of plasma biomarkers that are both sensitive and specific to neuropathology is required. Communication and support must be provided to patients when sharing biomarker information due to potential distress when assessing neuropsychiatric prognoses (pre-test counseling and post-test explanations). Objective associations of plasma biomarkers with neuropsychiatric syndromes can be important not only for patient information but also for use in clinical trials and for prediction of behavioral status at different timepoints in the continuum of dementia syndromes.

diagnoses with primary psychiatric syndromes, align clinical and research procedures, reduce costs, and benefit patients, caregivers, and healthcare systems with the cost-effective standard of care and research for NPS.

Next steps

With the ongoing efforts by the scientific community to understand AD (and other NDDs) as a biological construct² to facilitate therapeutic development, clinicians need to translate that information into easily understandable recommendations for their patients. In clinical studies, researchers should communicate closely and follow up with their participants.²⁵⁷ Autonomous decision-making in people with or at risk for dementia depends on promoting understanding by clearly delineating evidence of benefits, risks, and gaps in knowledge,²⁵⁸ including the translational aspects of plasma biomarkers of NPS.

Consistent selection of neuropsychiatric tests and their harmonization,²⁵⁹ as has been done with neuropsychological tests,²⁶⁰ might enable the use of mechanistically relevant biomarkers and treatment in line with their demonstrated informative or therapeutic value, with clear uniformity across different centers. More original studies with validated and harmonized methods to assess both NPS and plasma biomarkers in diverse cohorts are required,² including less-studied biomarkers of neuroinflammation and endothelial dysfunction.²⁶¹ Other factors that may also affect NPS measurement, such as informant characteristics for informant-rated tools, should be considered.²⁶² Agitation, apathy, depression, and psychosis are the most frequently studied NPS, for which there are syndromic criteria, though many others could be included in study protocols with large samples. Such studies should address all

NPS in different stages of different dementia syndromes and not only more frequent symptoms.

Important questions remain open, highlighting how much needs to be done with regards to biomarker development in this space. Whether some pre-existing or co-morbid condition underlying NPS symptoms significantly contributes to the trajectory of AD, or whether AD pathology occurring years before cognitive symptoms emerge affects processes that determine NPS are important questions to pursue further.

The associations of some less studied plasma biomarkers with cognition and neuropathology have already been demonstrated in the literature, but no studies with NPS may be currently found. These include circulating microRNAs²⁶³ and extracellular vesicles²⁶⁴ which should also be the target of future studies with behavioral associations.

Longitudinal studies that find associations between NPS and plasma biomarkers throughout the AD continuum while considering the presence of MBI are in high demand. These studies could suggest mechanistic relationships to elucidate how NPS and neuropathology evolve over time, and address if proper therapy may modify such relationships. Systematic reviews that identify, select, synthesize, and appraise all high-quality research evidence relevant to the associations of NPS with plasma biomarkers will be needed when more original studies are available. Actionable items have been drafted to achieve these goals (Table 2).

Implications and conclusion

The pathogenesis of behavioral symptoms is guided by neurochemical consequences of environmental factors and genetically-mediated proteinopathies. Objective associations of plasma biomarkers with NPS can be important not only for patient information during routine follow-up but also for use

in clinical trials and for prediction of behavioral status at different timepoints in the continuum of dementia syndromes.

The etiology of NPS and their underlying conditions should be determined with appropriate clinical workup, including plasma biomarkers that are minimally invasive by nature. This is important, as treatment is likely to vary depending on the underlying etiology. Nevertheless, it remains to be determined if treatment of later-life emergent and persistent NPS in preclinical and prodromal disease will change the disease course and delay or prevent incident behavioral and cognitive decline and dementia.
