## Abstract

Whilst machining heat is generated by the friction inherent into the sliding of the chip on the rake face of the insert. The temperature in the cutting zone of both the insert and the chip rises, facilitating adhesion and diffusion. These effects accelerate the insert wear, ultimately undermining the tool life. A number of methods have been therefore developed to control the heat generation. Most typically, metal working fluids (MWFs) are conveyed onto the rake face in the cutting zone, with negative implications on the contamination of the part. Many applications for instance in health-care and optics are often hindered by this contamination. In this study, microfluidics structures internal to the insert were examined as a means of controlling the heat generation. Conventional and internally-cooled tools were compared in dry turning of AA6082-T6 aluminium alloy in two 3<sup>3</sup> factorial experiments of different machining conditions. Statistical analyses supported the conclusion that the chip temperature depends only on the depth of cut but not on

the feed rate nor on the cutting speed. They also showed that the benefit of cooling the insert internally increases while increasing the depth of cut. Internally-cooled tools can therefore be particularly advantageous in roughing operations.

*Keywords:* Cutting temperature, internally-cooled tool, contamination-free machining, dry machining

---

## 1. Introduction

The large amount of heat generated in the cutting zone whilst machining is in many cases detrimental to the performance of the cutting tool. The generated heat can have a serious impact on the quality of the machined parts, causing them to be re-worked or scrapped. In conventional tools, the heat conducted into the insert can in turn pass into the tool holder. The consequent increase in the temperature of the tool holder may have an effect on the dimensional accuracy of the machined surface<sup>1</sup>. Many authors state that a reduction of the cutting zone temperature through strategic heat transfer improves the tool life<sup>2,3,4,5</sup>. The notion of dousing the cutter and work-piece with cooling fluid was first reported as a beneficial technique by Taylor<sup>6</sup>. Many metal working fluids (MWFs) are hazardous to the operator and can cause respiratory and dermatological illnesses<sup>7</sup>. A number of studies have been carried out highlighting that between 7-17% of the cost for a manufactured part is related to the coolant and the associated treatment activities<sup>2</sup>. Great effort has been made to remove the coolant completely (dry machining)<sup>2,3,4</sup> or just to reduce the used amount (Minimum Quantity Lubrication, MQL)<sup>3</sup>. Removing flood cooling appears beneficial to the safe-

19 guard of the environment and of the machine operator health, while also  
20 providing a financial advantage to the manufacturer. However, the funda-  
21 mental machining requirement to manage the temperature in the cutting  
22 zone must always be confronted. The potential hazards associated with high  
23 cutting temperatures can include tool failure, slowed production rates and  
24 geometrical inconsistency of the machined part leading to higher production  
25 cost<sup>5</sup>.

26 The desirable end result of the removal of MWFs from metal cutting is  
27 the opportunity to carry out contamination-free machining. There may be  
28 applications where an external coolant supply has prohibitive contraindica-  
29 tions. This would be for example the case when machining sensitive materials  
30 for optics or bio-medical applications or when machining harmful materials  
31 such as radioactive materials.

32 In dry contamination-free machining, the most significant issue is the ele-  
33 vated cutting temperatures hindering the tool life and thus increasing the pro-  
34 duction cost<sup>2</sup>. The aim of this investigation is to compare dry contamination-  
35 free machining with a conventional and with an internally-cooled tool to  
36 address the issue of raised cutting temperatures.

37 The shearing of material by the cutting tool generates a large amount of  
38 heat at the tool-chip interface<sup>8</sup>. Numerical models and simulations suggest  
39 temperatures at this interface can be as high as 400°C whilst machining alu-  
40 minium alloys<sup>9,10</sup>. At these temperatures, specific microstructural changes  
41 occur<sup>11</sup>. According to Quan *et al*<sup>12</sup>, between 60-95% of this heat is dissi-  
42 pated into the chips formed by the cutting process. High temperature in this  
43 region also creates a rapid formation of a Built-Up-Edge (BUE), where the

44 work-piece material adheres to the surface of the tool making it blunt. BUE  
45 affects the quality of the part, increases forces and the cutting temperature.  
46 The complexities within the cutting region with regards to abrasion, adhe-  
47 sion and diffusion are also well documented<sup>13,14</sup>. Adhesion of the work-piece  
48 material to the tool is highly influenced by the temperature in the cutting  
49 zone<sup>14,15</sup>. Subsequent tool wear and BUEs cause additional heat generation.  
50 This cycle continues until the sharp edge of the tool can no longer effectively  
51 shear the material in the cutting zone. The tool ploughs in the work-piece  
52 compromising the surface finish of the part. Another detrimental but equally  
53 destructive wear mechanism is chipping/notching of the cutting edge. This  
54 can take place due to a rapid disconnection of the BUE<sup>13</sup>. The high tem-  
55 perature within the interface region must therefore be controlled. Abrasive  
56 wear is unavoidable in cutting as the process is essentially based on shearing  
57 the work-piece material. In effective management of the cutting tempera-  
58 ture, the temperature should be reduced to a magnitude that minimises the  
59 degree of adhesive and diffusive wear.

60 New approaches to thermal control cover the application of non-traditional  
61 cooling media and the methods by which it is applied to the work-piece.  
62 Among these media, the usage of cryogenic coolants likes liquid nitrogen  
63 ( $N_2$ ) and carbon dioxide ( $CO_2$ ) has been reported. Among these methods,  
64 high pressure jet cooling has also been studied<sup>16</sup>. However, in all of these  
65 methods the coolant is a consumable and in most cases it is applied in an  
66 open loop system. For the cryogenic examples the coolant evaporates and  
67 cannot be collected and re-circulated.

68 A solution to this age-old problem is the notion of an internally-supplied

69 coolant within a closed loop system. Such a system was first described in  
70 the seventies<sup>17,18</sup> and has then been attempted many times using a plethora  
71 of different designs and methods<sup>19,20,21</sup>. Fundamentally, a fluid is pumped  
72 through the tool shank, into a heat exchanger module situated beneath the  
73 cutting insert and back out through the tool shank. Channelling heat into  
74 the tooling may seem counter intuitive due to potential problems that this  
75 may cause (higher wear rates, diffusion, adhesion, tool expansion). But the  
76 internal fluid will enable the heat transfer from the cutting zone to an ex-  
77 ternal heat sink much more quickly than the time needed for these potential  
78 problems to arise within the tooling.

79 Other researchers<sup>22</sup> advocate the addition of internal cooling to tool sys-  
80 tems as a means of reducing the temperature of the cutting tool. Tungsten  
81 carbide is a relatively poor heat conductor, so the heat generated during  
82 cutting cannot readily be transferred through conventional tungsten carbide  
83 tools. The internal flow of coolant acts as an express way for the heat con-  
84 ducted from the tool-chip interface zone into the tool to an external heat  
85 sink.

86 As much as 95% of the heat generated during cutting has been reported  
87 to dissipate into the chip<sup>12</sup>. Measuring the temperature of the chip appeared  
88 therefore a sensible choice to establish the effect of cooling the tool inter-  
89 nally. Any decrease of the measured chip temperature during cutting with  
90 the internally-cooled tool compared to conventional inserts would suggest  
91 that the internally-cooled tool is effective in transferring a significant frac-  
92 tion of the heat generated at the chip-rake face interface during cutting.

93 Many authors have attempted to measure the temperature within the

94 cutting zone using an array of different techniques. The most popular of  
95 these is the embedded thermocouple<sup>8</sup>. This would be easy to implement  
96 using a standard monolithic cutting insert. However, in this investigation  
97 the internal geometry of the cooling structure makes this option not viable.  
98 The thermocouple is required to be as close to the cutting tip as possible.  
99 But the cooling channels are also required to be as close to the cutting tip  
100 as possible in order to maximise the effect of the internal coolant. There is a  
101 very large thermal gradient experienced during cutting and so a thermocou-  
102 ple which is placed more than a few millimetres from the tool tip will not give  
103 an accurate measurement of the cutting temperature. Another circumstance  
104 that would deter investigators from the use of embedded thermocouples is  
105 the change in the dynamics of heat transfer within the tool inserts caused  
106 by the thermocouple itself and the necessary hole<sup>8,23</sup>. Another method used  
107 in previous studies is the tool-work thermocouple or dynamic thermocou-  
108 ple<sup>24</sup>. This is difficult to use due to the relatively low electrical conductivity  
109 of the tungsten carbide inserts. In this study, a non-contact infrared py-  
110 rometer was used to measure the chip temperature. This method has been  
111 successfully used by previous studies to validate numerical and finite element  
112 analysis (FEA) models where the tool-chip interface temperatures have been  
113 calculated<sup>25</sup>. This method is deemed difficult to use due to the fluctuating  
114 emissivity of materials such as metals. However, once the pyrometer has  
115 been correctly calibrated using the black body technique, the measurements  
116 can be considered fairly reliable.

## 117 2. Experimental set up and cutting trials

118 The intent of testing dry cutting conditions led to the selection of a ma-  
119 terial for the test parts that can facilitate cutting operations. An aluminium  
120 alloy was considered because its machinability characteristics make the wear  
121 resistance properties of the insert, which is the central critical part of the  
122 set-up, less demanding. A reduced number of conventional and internally-  
123 cooled inserts was therefore needed than the number that would have been  
124 required in machining other materials, say for example steel. The aluminium  
125 alloy AA6082-T6 with relatively high silicon and magnesium content (0.7-1.3  
126 and 0.6-1.2 % in weight, respectively) was selected due to its ready availabil-  
127 ity and widespread usage in several applications. One cylindrical bar was  
128 machined in cutting trials with a conventional tool insert and a second bar  
129 was instead machined in cutting trials with the internally-cooled tool. Di-  
130 ameter and length of the two AA6082-T6 blanks were 65 mm and 450 mm  
131 respectively. The length of the bar was sufficient to observe in each trials the  
132 establishment of a steady measured temperature of the chip surface. A mi-  
133 nor drawback was that the high aspect-ratio of the blank required a tailstock  
134 to be used on the lathe. The cutting trials were performed using an Alpha  
135 Colchester Harrison 600 Group CNC lathe. In Figure 1, the machine set-up  
136 is displayed. In the figure the tool system, the work-piece and pyrometer  
137 used to measure the chip temperature are shown.

138 [Figure 1 about here.]

139 Internally-cooled tools were designed and manufactured by modifying com-  
140 mercially available tools. This approach greatly reduced the development

141 time and cost. The designed internally-cooled cutting tool consists of three  
142 main components: (a) the modified cutting insert, (b) the cooling adaptor  
143 accommodating the micro channel and (c) the tool holder with the inlet and  
144 the outlet ports. A representative geometrical model of the modified cutting  
145 insert assembled onto the cooling adaptor is displayed in Figure 2.

146 [Figure 2 about here.]

147 The selected cutting insert was square in shape, without chip-breaker and  
148 made of tungsten carbide (WC) with 6% cobalt (SNUN120408, produced by  
149 Hertel). The insert was purpose-machined by electro-discharge machining  
150 (EDM) to fabricate a squared bottle-cap shape part with 1 mm wall thick-  
151 ness. It was then attached to the cooling adaptor in such a way that an empty  
152 cavity near the cutting zone is created between the insert and the adaptor.  
153 This cavity hosts the flow of coolant during operations. The cooling adaptor  
154 was machined on a five-axis micro-milling machine to accommodate ad hoc  
155 designed micro channels of 800  $\mu\text{m}$  diameter to enable coolant recirculation  
156 inside the above-mentioned cavity. The module made of the insert and the  
157 cooling adaptor was then assembled with a tool holder. An off-the-shelf tool  
158 holder (CSBNR 2525M 12-4, produced by Sandvik) was modified so that  
159 inlet and outlet tubes for the internal-coolant could be fixed on the bottom  
160 and side surfaces, respectively. Figure 3 displays a production phase of the  
161 cooling adaptor on a five-axis micro-milling machine, the squared bottle-cap  
162 insert, the cooling adaptor and the assembled tool system.

163 [Figure 3 about here.]

164 The coolant used in the experiment was pure water with corrosion inhibitor  
165 which was pumped in a closed loop system by a micro diaphragm liquid  
166 pump (NFB 60 DCB made by KNF- Neuberger). The pump can deliver up  
167 to 1.2 L/min with twin heads which allows coolant speed to be varied and  
168 controlled. In this study, for simplicity the coolant speed was kept constant  
169 at 0.3 L/min.

170 The experimental set-up was complemented with a thermal sensor, a data  
171 acquisition system and a data processing software. The thermal sensor used  
172 in this study was a laser pyrometer with minimum spot size of the beam  
173 equals to 0.45 mm ( $\mu$ -Epsilon, model CTLM3- H1 CF2). The pyrometer was  
174 fixed at 150 mm above the cutting insert and pointed to a single point on the  
175 insert's rake face about 1 mm away of the cutting edge (cf Figure 1). The  
176 temperature measurements were acquired at 1000 Hz and then transferred to  
177 a computer-based acquisition system. Dedicated software (Compact connect)  
178 provided by the pyrometer manufacturer enabled to display dynamically the  
179 measured temperature values. Also, in this software, the emissivity of the  
180 target surface could be set. In this study, the emissivity of the target surface  
181 has been determined as 0.78.

182 The values of the instantaneous chip temperatures recorded during all  
183 the cutting trials appeared to achieve a steady state condition. In the at-  
184 tempt of identifying unambiguously this state, a procedure has been devised.  
185 A unique value of temperature has then been associated with the identified  
186 steady state for each cutting trial. In this way, high reproducibility of the  
187 steady state temperature is assured. The procedure involved three stages.  
188 First, the start and the end of each machining operation were uniquely identi-

189 fied by recording the instants of time when the measured temperature exceed  
190 the minimum temperature measurable by the pyrometer (150 °C). Second,  
191 the interquartile range of the temperature distribution measured between the  
192 identified start and end was calculated. Third, the average of the temper-  
193 atures measured within the interquartile range is computed and defined as  
194 the steady state temperature of the chip. Figure 4 illustrates the procedure.  
195 This steady state chip temperature measured during a machining trials is  
196 taken as representative of all the thermal information available about the  
197 trial performed in pre-specified, designed machining conditions.

198 [Figure 4 about here.]

### 199 **3. Design of the Experiment**

200 During machining operations with the internally cooled tool, the tem-  
201 perature ( $T$ ) of the chip was measured in a set of experimental conditions  
202 identified by three controllable technological variables: the depth of cut ( $d$ ),  
203 the feed rate ( $f$ ) and the cutting speed ( $v$ ). Due to their numerical nature,  
204 these variables have been considered as continuous rather than categorical.  
205 For each variable three values were considered identifying a region of inter-  
206 est in the space ( $d, f, v$ ). Symbols, units and values of the technological  
207 variables are presented in Table 1.

208 [Table 1 about here.]

209 The number of the different experimental conditions (treatments) was there-  
210 fore  $3^3$ , i.e. 27. For each of the 27 treatments the cutting test was replicated  
211 three times, thus giving a total of 81 tests. The run order of the treatments

212 was generated by assigning each of them a unique label and then randomly  
213 drawing a sequence of 27 labels from all the possible 27! label permutations.  
214 Once the machine was set up according to a specific treatment, all the three  
215 cutting tests for that treatment were performed. Changing from one experi-  
216 mental condition to another was a time consuming operation that prohibited  
217 to randomise fully the order of the 81 tests. If some nuisance event occurred  
218 while performing the three tests for a specific treatment, then its potential  
219 effect on the chip temperature would have been erroneously attributed to the  
220 treatment. However, the controlled conditions of the laboratory where the  
221 tests took place limited the likelihood for such random nuisance events to  
222 occur.

#### 223 4. Modelling and Statistical Analysis

224 The main objective of this section is to construct a quantitative functional  
225 relationship (i.e. a model) between  $T$  and  $(d, f, v)$  in a region of the three-  
226 dimensional technological space  $(d, f, v)$ .

227 In Figure 5, the 81 test results are grouped by depth of cut. To make the  
228 figure clearer, overlapping points at the same depth of cut were separated by  
229 adding a random small amount to each abscissa of the points (jittering pro-  
230 cedure)<sup>26</sup>. The average chip temperature for each depth of cut is designated  
231 with a triangle, whereas the median with a square. Mean and median both  
232 suggest that the chip temperature increases linearly with the depth of cut.  
233 The boxplot with notches in the same figure further confirmed the initial  
234 graphical intuition.

235 [Figure 5 about here.]

236 For each group of data (i.e. for the  $T$ s measured at one of the three depths  
237 of cut), each box is made of three horizontal segments, identifying the first  
238 quartile, the median and the third quartile of the  $T$ s, respectively. two  
239 notches (i.e. two vertical ‘v’ with apexes ending on the median segment) are  
240 calculated and drawn at each side of the boxes. If the notches of two boxes  
241 do not overlap, the median of the two groups are significantly different at  
242 about 95 % confidence level<sup>27</sup>. The dashed vertical lines in the same figure  
243 (called whiskers) extend 1.5 times the value of the interquartile range. They  
244 are meant to identify values lying far apart from the majority of the data  
245 in a group. In Figure 5, it is noticed that there are three such points when  
246  $d = 0.5$  mm. A further investigation did not highlight any assignable cause  
247 for the occurrence of these values. So these three experimental results were  
248 treated as unlikely but possible events. Thus, they were not excluded from  
249 the analysis.

250 In Figure 6, the chip temperatures have been grouped by feed rate and  
251 by cutting speed. Opposite to Figure 5, these boxplots do not suggest any  
252 significant difference in the median chip temperature when the feed rate is  
253 changed. Likewise, changing the cutting speed does not appear to affect  $T$   
254 significantly. Five extreme points appears in the two boxplots of Figure 6.  
255 Yet, as before, further investigation did not reveal any assignable cause of  
256 their outlying. These points were therefore not excluded from the analysis.  
257 In the same figure, the variability of the chip temperature appears dubiously  
258 constant. In particular, the group of feed rate 0.1 mm/rev is of difficult  
259 interpretation due to the simultaneous presence of 3 extreme points and a  
260 noticeably small interquartile range relatively to the other groups.

261

[Figure 6 about here.]

262 No significant second order interaction effect of  $(d, f, v)$  on  $T$  was appar-  
263 ent in the examined interaction plots. To select a model to fit the data, a  
264 step-wise procedure with forward selection of the independent variables was  
265 followed<sup>28</sup>. Starting from the model with only the mean chip temperature  
266 and no variables included (also known as the null model), models with in-  
267 creasing complexity are considered by adding one variable at a time. When a  
268 variable is included, the p-value of the F-test assessing the significance of the  
269 decrease in deviance yielded by the inclusion is evaluated. If the reduction of  
270 deviance (i.e. the sum of the squares of the residuals alias the unexplained  
271 variation in the response variable) is statistically significant, then the corre-  
272 sponding technological variable is included into the model. Else, it is not (cf  
273 pages 323-329 in Crawley<sup>26</sup>, with adjustments). Second degree terms of two  
274 variables are included in the model only if each of the single variables are  
275 per se significant (marginality restrictions)<sup>29,28</sup>. The results of the variable  
276 selection procedure are shown in Table 2. The calculations were performed  
277 with R, a language and environment for statistical computing<sup>30</sup>.

278

[Table 2 about here.]

279 As a consequence of Table 2, the feed rate and the cutting speed are not in-  
280 cluded in the proposed statistical model, which is synthesised by the following  
281 equation:

$$T_i = \beta_0 + \beta_1 d_i + \epsilon_i \quad (1)$$

282 Equation 1 describes the expected chip temperature versus the depth of cut  
283 as a straight line. The index  $i = 1, 2, \dots, 81$  identifies each of the actual cases

284 in the data available. The terms  $\epsilon_i$  are random variables that, without losing  
 285 generality, are assumed to be independent and identically distributed with  
 286 mean zero and constant variance  $\sigma^2$ . If they are also normal, further analysis  
 287 of the model parameters are facilitated. The 2+1 parameters ( $\beta_0$ ,  $\beta_1$  and  
 288  $\sigma$ ) have been estimated with the ordinary least-squares method (OLS) using  
 289 the functions available in R<sup>30</sup>. A more complex model including a quadratic  
 290 term in the depth of cut was also considered, namely:  $T_i = \beta_0 + \beta_1 d_i + \beta_1 d_i^2 +$   
 291  $\epsilon_i$ . As shown in Table 3, the model with the second degree term in  $d$  (i.e.  
 292  $d^2$ ) does not lead to a significant reduction of the unexplained variation of  
 293 the response, when compared with the straight-line model (p-value=9.6 %).  
 294 Thus the term  $d^2$  is excluded from equation 1.

295 [Table 3 about here.]

296 The model of equation 1 was tested for lack of fit<sup>28</sup>. From a practical point  
 297 of view, this means that If  $\hat{\sigma}$  for the model is not significantly larger than  
 298 the estimated repeatability standard deviation of the temperature measure-  
 299 ment procedure, then the assumption that the model fits the data cannot be  
 300 rejected. The results of the tests are displayed in Table 4. A p-value=9.62  
 301 % shows that the lack of fit is not significant. The estimated repeatabil-  
 302 ity standard deviation of the chip temperature measuring procedure equals  
 303  $16.3 \text{ }^\circ\text{C} \left( \sqrt{\frac{20792}{78}} \text{ }^\circ\text{C} \right)$ , whereas the estimated standard deviation of the errors  
 304 is  $16.5 \text{ }^\circ\text{C} \left( \sqrt{\frac{21548}{79}} \text{ }^\circ\text{C} \right)$ .

305 [Table 4 about here.]

306 Graphically, the test for lack of fit shows that the difference between the fitted  
 307 and the mean points for each of the cutting depths tested is not significant

308 (cf the x and the triangular points in Figure 5).

309 The estimated intercept and slope are displayed in Table 5 together with  
310 their estimated standard deviations (i.e. standard errors).

311 [Table 5 about here.]

312 The differences between the measured temperature values and the corre-  
313 sponding predictions of the model (fitted values) are referred to as residuals.  
314 If the errors  $\epsilon_i$  are independent and with equal variance, then the residuals  
315 should not exhibit any pattern nor varying scatter, regardless of how they  
316 may have been grouped. In Figure 7 the residuals are displayed versus the  
317 fitted temperature values and versus the depth of cut (both jittered). The  
318 group means are also displayed as triangular points (there are 3 groups of 27  
319 data points in each of the two diagrams).

320 [Figure 7 about here.]

321 Figure 7 raises the suspicion that the variance of the errors is not constant.  
322 The residuals with larger fitted values appear to have lower dispersion than  
323 the others. Due to the proportionality of the fitted temperature and the  
324 depth of cut (cf equation 1), the residuals also appear to have lower varia-  
325 tion when the depth of cut is larger (Figure 7). New models were therefore  
326 considered to account for heteroscedastic errors (cf the classes of variance  
327 functions in the R package *nlme*<sup>31,32</sup>). The exponential variance function  
328 (i.e. `varExp()`) offered the best fitting of the model to the data in terms of  
329 Akaike Information Criterion (AIC)<sup>32</sup>. The variance of the errors is modelled  
330 by this class as described in the following equation:

$$\text{Var}(\epsilon_i) = \sigma_a^2 e^{2\delta d_i} \quad (2)$$

331 In equation 2,  $\sigma_a$  and  $\delta$  are two parameters in the model that are estimated  
332 using the restricted maximum likelihood method (REML) as implemented in  
333 the `glis()` function of `nlme`. The estimates are displayed in Table 6 together  
334 with approximate 95 % confidence intervals for the same estimated parame-  
335 ters.

336 [Table 6 about here.]

337 The difference of the intercepts and the slopes in the two models does not  
338 appear significant. The corresponding confidence intervals overlap (cf Ta-  
339 bles 5 and 6). Yet Figure 8 shows that equation 2 successfully accounts for  
340 the variance structure of the errors.

341 [Figure 8 about here.]

342 Similar analyses have been performed on data collected in designed machin-  
343 ing trials with an uncooled tool in the same experimental conditions. These  
344 analyses led to the same conclusion that only the depth of cut is a signif-  
345 icant explanatory variable for the the chip temperature. The fitted model  
346 can be described with the same terms present in Equation 1. The OLS es-  
347 timates of the model parameters and their 95 % confidence intervals under  
348 the hypothesis of normally distributed errors are displayed in Table 7.

349 [Table 7 about here.]

350 The confidence intervals of the intercept and the slope of the model for the  
351 internally-cooled tool do not overlap with the corresponding confidence inter-  
352 vals calculated for the conventional tool (cf Table 6 and 7) . This is a strong

353 evidence that the internal microfluidics structures are effective in changing  
354 the measured thermal characteristics of the chip.

355 Opposite to the case of the cutting trials with the internally cooled tool,  
356 in Figure 9 the residuals do not exhibit any pattern of variance increasing  
357 with the depth of cut (Figure 7).

358 [Figure 9 about here.]

## 359 **5. Practical implications of the findings**

360 The Analysis in the previous section provides quantitative evidence that  
361 for the internally-cooled tool the dispersion of the temperature measurement  
362 results is decreasing while depth of cuts and chip temperatures increase (cf.  
363 Figure 7). A possible reason can be identified in the measuring system of  
364 the chip temperature. The diameter of the pyrometer laser beam was in fact  
365 0.45 mm. So when measuring the chip temperature, if the width of the chip  
366 is smaller than 0.45 mm, the part of the laser beam that exceeds the size of  
367 the chip may hit upon part of the tool rake face. If this interpretation holds,  
368 then for depth of cut less than 0.45 mm the chip temperature measurements  
369 may be biased.

370 The potential bias in measuring the temperature may be the reason why  
371 the straight lines in Figure 10 intersect. These continuous and dashed lines in  
372 Figure 10 represent the models fitted to the the experimental results from the  
373 cutting trials with an internally-cooled and a conventional tool, respectively.  
374 A possible different interpretation of the intersection between the two lines  
375 is that the internally-cooled tool is indeed effective in reducing the chip tem-  
376 perature only beyond a critical depth of cut. Further investigation outside

377 the scope of this investigation is required to clarify this point.

378 [Figure 10 about here.]

379 This constantly varying exposed area of the rake face to the laser beam  
380 may be the cause of the inflated variability of the errors at lower depth of  
381 cut. However, it has been shown above that the changed structures of the  
382 errors variance does not affect significantly the OLS estimates of the intercept  
383 and of the slope of the model.

384 This consideration may also help to explain the rather unexpected circum-  
385 stance that at  $d = 0.20$  mm six measured chip temperature values obtained  
386 with the internally cooled tool are higher than any other temperature mea-  
387 sured when machining at the same depth of cut with a conventional tool  
388 (Figure 10).

389 The same set-up for measuring the temperature has been used also in the  
390 experiment with a conventional tool not internally cooled. Yet, in that case  
391 no reduced dispersion of the temperature measurement results was observed  
392 when increasing the depth of cut (cf. Figure 9). The suspicion may thus arise  
393 that the increased fluctuation of temperature at small depths of cut may be  
394 a typical characteristic of the material removal mechanism with an internally  
395 cooled tool. Further study would be needed to support this intuition.

396 The observation of Figure 10 does however remove any doubt that at  
397  $d = 0.50$  mm an internally-cooled turning tool is significantly effective in  
398 reducing the chip temperature. The extrapolation (cf Crawley<sup>26</sup>, page 412) of  
399 the two models of Figure 10 to depths of cut larger than 0.50 mm supports the  
400 speculative expectation that the internally-cooled cutting tool is increasingly  
401 effective in reducing the chip temperature.

## 402 **6. Conclusions**

403 This study aimed at exploring the thermal characteristic of cutting pro-  
404 cesses with a purpose-built, internally-cooled prototype of a tool system.  
405 Chip temperature in turning of AA6082-T6 aluminium alloy with conven-  
406 tional and internally-cooled turning tools were compared in two separated  $3^3$   
407 factorial experiments in the space of the technological variables depth of cut,  
408 cutting speed and feed rate. No external coolant was used in the machining  
409 trials.

410 Linear statistical models with homoscedastic and heteroschedastic errors  
411 were fitted to the experimental results. OLS and REML methods were respec-  
412 tively used to estimate the parameters of the fitted models.

413 The statistical analyses showed that the measured chip temperature ap-  
414 pears to depend significantly only on the depth of cut but not on the feed  
415 rate nor on the cutting speed.

416 These analyses also suggest that, as the depth of cut is increased, the  
417 internally-cooled tool is incrementally more effective in reducing the chip  
418 temperature than the conventional tool is. Consequently, when no MWFs  
419 are used, internally-cooled tools appear to be potentially advantageous over  
420 conventional tool in roughing operations.

421 In cutting trials with internally-cooled tools, a significantly increased fluc-  
422 tuation of the chip temperature has been identified when decreasing the depth  
423 of cut.

## 424 **Acknowledgements**

425 This research was performed within the scope of the collaborative research  
426 project 'Self-learning control of tool temperature in cutting processes'(CONTEMP)  
427 funded by the European Commission 7th Framework Programme (Contract  
428 number: NMP2-SL-2009-228585). The authors gratefully acknowledge the  
429 committed support of all the technical staff in the AMEE Department at  
430 Brunel University. Particular gratitude goes to Mr Paul Yates for his help in  
431 the cutting trials.
